Abstract: Although C\textsubscript{2}H\textsubscript{5}OH and CH\textsubscript{3}OCH\textsubscript{3} are isomeric compounds, C\textsubscript{2}H\textsubscript{5}OH is much more efficient for NO\textsubscript{x} reduction than CH\textsubscript{3}OCH\textsubscript{3}. In situ diffuse reflectance infrared Fourier transform spectroscopy was used to study the reaction mechanism. The enolic species derived from the partial oxidation of C\textsubscript{2}H\textsubscript{5}OH over Ag/Al\textsubscript{2}O\textsubscript{3} plays a crucial role in the formation of –NCO species during the selective catalytic reduction (SCR) of NO\textsubscript{x} by C\textsubscript{2}H\textsubscript{5}OH. The high reactivity of the enolic species results in high surface concentration of –NCO species and high efficiency of NO\textsubscript{x} reduction when C\textsubscript{2}H\textsubscript{5}OH was used as the reductant. In the case of CH\textsubscript{3}OCH\textsubscript{3}, the formate species as the main intermediate has low activity for the formation of –NCO species, which results in the relatively low efficiency during the SCR of NO\textsubscript{x}.

Key Words: silver; alumina; nitrogen oxide; selective catalytic reduction; ethanol; methyl ether; in situ diffuse reflectance infrared Fourier transform spectroscopy; enolic species; formate species; isocyanate species

1 Experimental

1.1 Preparation and activity test of the catalyst

The 4% Ag/Al\textsubscript{2}O\textsubscript{3} catalyst was prepared by an impregnation method according to the literature [6]. The catalytic activity was measured in a fixed-bed reactor by passing a gaseous mixture of 0.08% NO, 0.1565% reductant, and 10% O\textsubscript{2} in
N₂ balance at a total flow rate of 2 L/min over 0.6 g catalyst \((W/F = 0.018 \text{ g/s/ml}, \text{ GHSV} = 50000 \text{ h}^{-1})\). An aqueous C₂H₅OH solution was fed into the gas stream using a syringe pump and vaporized using a coiled heater at the inlet of the reactor. NO₃ conversion was analyzed online using a chemiluminescence NO/NO₂/NO₃ analyzer (42C-HL, Thermo Environmental Instruments Inc.).

1.2 In situ DRIFTS analysis

In situ DRIFTS spectra were recorded on a NEXUS 670 FT-IR spectrometer equipped with a smart collector and an MCT/A detector cooled by liquid N₂. The catalyst (0.03 g) was finely ground and placed in a ceramic crucible. Prior to each experiment, the catalyst was heated to 873 K in a flow of 10% O₂/N₂ for 60 min and then cooled to the desired temperature. A spectrum of the catalyst in the flow of N₂ + O₂ was taken as the background. The overall gas flow rate was 300 ml/min. All the spectra were measured at a resolution of 4 cm⁻¹ with an accumulation of 100 scans.

2 Results and discussion

2.1 Comparison of the catalytic activity of Ag/Al₂O₃ during the SCR of NOₓ by C₂H₅OH and CH₃OCH₃

Fig. 1 compares the reduction of NO₃ by C₂H₅OH and CH₃OCH₃ over the Ag/Al₂O₃ catalyst. When C₂H₅OH was used as the reductant, NO₃ was reduced effectively within the whole temperature range, and the maximum NO₃ conversion was 99.6% at 690 K. In contrast, there was a relatively low conversion was only 22.5%. These results indicate that the NO₃ conversion is strongly influenced by the structure of the reductants. It has been widely accepted that hydrocarbon activity in the SCR of NO₃ increases with the number of carbon atoms and the degree of unsaturation [13]. Although C₂H₅OH and CH₃OCH₃ are isomeric compounds, CH₃OCH₃ is less effective compared with C₂H₅OH for the SCR of NO₃. This difference can be explained on the basis of different mechanisms for each case and it is described in the following sections.

2.2 In situ DRIFTS study of the SCR of NOₓ by C₂H₅OH and CH₃OCH₃ over Ag/Al₂O₃

The difference in behavior between C₂H₅OH and CH₃OCH₃ for the SCR of NO₃ over Ag/Al₂O₃ was investigated using the in situ DRIFTS method. The in situ DRIFTS spectra of Ag/Al₂O₃ were recorded at various temperatures in a steady state after exposing Ag/Al₂O₃ to NO + O₂ + C₂H₅OH or to NO + O₂ + CH₃OCH₃. The reaction conditions are the same as those in the measurement of activity.

Fig. 2(a) shows the in situ DRIFTS spectra of the Ag/Al₂O₃ catalyst in a flow of NO + O₂ + C₂H₅OH. It can be seen that several peaks appeared in the region of 1700–1300 cm⁻¹. Based on the previous study [12, 14], the bands at 1585 and 1304 cm⁻¹ are due to the adsorbed bidentate nitrate species (NO₃⁻), and the peaks at 1579 and 1468 cm⁻¹ are associated with the acetate species (CH₃COO⁻), while the peaks at 1633, 1416, and 1336 cm⁻¹ are assigned to the enolic species (RCH=CH–O–), which was predominantly formed due to the partial oxidation of C₂H₅OH. Furthermore, a very strong peak appeared at 2233 cm⁻¹, which is assigned to the –NCO species. It has been widely accepted that –NCO species is the key intermediate in the SCR of NO₃ over Ag/Al₂O₃, and its high productivity results in the high efficiency of NO₃ reduction [9–12, 14]. As can be seen from Fig. 2(a), the intensities of nitrate species and enolic species decreased gradually with the increase in reaction temperature, while the intensity of –NCO species increased gradually with the reaction temperature. At 673 K, the intensity of –NCO species reached the maximum, indicating that the system underwent a quick and efficient reaction, which is in good agreement with the results of the activity study.

Fig. 2(b) represents the in situ DRIFTS spectra of the Ag/Al₂O₃ catalyst in a flow of NO + O₂ + CH₃OCH₃ in a steady state at various temperatures. Unlike the C₂H₅OH-containing system, when the Ag/Al₂O₃ catalyst was exposed to a NO + O₂ + CH₃OCH₃ mixture under the same experimental conditions, the peak due to the enolic species (around 1633 cm⁻¹) was not observed, whereas very strong peaks appeared at 1591 and 1379 cm⁻¹, which are assigned to ν₂(OCO) and ν₁(OCO) of formate species, respectively. In addition, the peaks at 1585 and 1304 cm⁻¹ are attributed to the bidentate nitrate species, and the peak at 1562 cm⁻¹ corresponds to the monodentate nitrate species, while the peaks at...
1616 cm\(^{-1}\) is associated with bridge nitrate species \[14\]. The peak at 1392 cm\(^{-1}\) is associated with δ(C–H) of the formate species \[12,14\], while the very weak peak at 2239 cm\(^{-1}\) is due to the –NCO species. Although the formate species is the main surface species on Ag/Al\(_2\)O\(_3\), it has low reactivity with NO\(_3^–\) or NO + O\(_2\) to form –NCO species, which may account for its relatively low efficiency for the SCR of NO\(_x\). This result is in good agreement with that of the activity study.

The surface adsorbed species formed on Ag/Al\(_2\)O\(_3\) during the partial oxidation of C\(_2\)H\(_5\)OH or CH\(_3\)OCH\(_3\). Fig. 3 shows the in situ DRIFTS spectra of Ag/Al\(_2\)O\(_3\) at various temperatures in a steady state after exposing to the two reductants and O\(_2\). As for C\(_2\)H\(_5\)OH, the peaks at 1633, 1416, and 1336 cm\(^{-1}\) are attributed to the enolic species, and the peaks at 1579 and 1466 cm\(^{-1}\) are assigned to the acetate species. In the case of CH\(_3\)OCH\(_3\), the formate species (1595, 1379, and 1392 cm\(^{-1}\)) is predominant during its oxidative reaction. This comparative study shows that partial oxidation of CH\(_3\)OCH\(_3\) is different from that of C\(_2\)H\(_5\)OH. It is concluded that the different partial oxidation reactions of C\(_2\)H\(_5\)OH and CH\(_3\)OCH\(_3\) over Ag/Al\(_2\)O\(_3\) results in the different mechanisms for the SCR of NO\(_x\).

2.3 In situ DRIFTS study of the partial oxidation of reductants over Ag/Al\(_2\)O\(_3\)

To elucidate the diverse effects of C\(_2\)H\(_5\)OH and CH\(_3\)OCH\(_3\) in the SCR of NO\(_x\), in situ DRIFTS was used to investigate
2.4 Reactivity of the surface adsorbed species over Ag/Al₂O₃

To obtain further information with regard to the reactivity of the surface adsorbed species during the SCR of NOₓ over Ag/Al₂O₃, in situ DRIFTS was used to evaluate the dynamic performance of these surface adsorbed species. Fig. 4 shows the dynamic changes of in situ DRIFTS spectra of the two reductants and O₂ over Ag/Al₂O₃ as a function of time in a flow of NO + O₂ at 673 K. When the catalyst was exposed to C₂H₅OH + O₂ for 60 min (Fig. 4(a)), very strong peaks corresponding to enolic species appeared at 1633, 1416, and 1338 cm⁻¹, and the peaks corresponding to acetate species were also observed at 1579 and 1466 cm⁻¹. Switching the feed gas to a flow of NO + O₂ resulted in a sharp decrease in the intensity of the enolic species. Meanwhile, a new –NCO peak appeared at 2229 cm⁻¹, and its intensity initially increased and then decreased. When the enolic species was completely consumed, a large amount of nitrates and acetate species became the dominant surface species on Ag/Al₂O₃, while the surface concentration of –NCO was very low. This result indicates that the enolic species effectively react toward NO + O₂ to form –NCO species compared with the acetate species. As a result, it is the enolic species rather than the acetate species that plays a crucial role in the formation of –NCO by the reaction with NO + O₂.

The same experiment was carried out by exposing the catalyst to a flow of CH₃OCH₃ + O₂. As shown in Fig. 4(b), the peaks of the formate species (1595, 1392, and 1381 cm⁻¹) were very strong after Ag/Al₂O₃ was exposed to CH₃OCH₃ + O₂ at 673 K, and switching the feed gas to NO + O₂ resulted in a decrease in the intensity of the formate species. Simultaneously, a very weak –NCO peak (2239 cm⁻¹) was observed. The results suggest that the formate species is the main intermediate in the formation of –NCO species during the SCR of NOₓ by CH₃OCH₃ over Ag/Al₂O₃. This comparative study shows that enolic species has much higher reactivity toward NO + O₂ to form –NCO species compared with the formate species over Ag/Al₂O₃.

Fig. 5 shows the dynamic changes of in situ DRIFTS spectra of NO + O₂ over Ag/Al₂O₃ in a flow of the two reductants and O₂ at 673 K, respectively. Exposing the Ag/Al₂O₃ catalyst to a flow of NO + O₂ resulted in the formation of four peaks (1254, 1566, 1298, and 1589 cm⁻¹). As shown in Fig. 5(a), the peaks at 1254 and 1566 cm⁻¹ are assigned to the monodentate nitrate species, and the peaks at 1298 and 1589 cm⁻¹ are associated with the bidentate nitrate species. Switching the feed gas from NO + O₂ to C₂H₅OH + O₂ led to a drastic decrease in the peak intensity of the monodentate nitrate species. In contrast, the intensity of the bidentate nitrate species slowly decreased, suggesting that monodentate nitrate species has a higher reactivity than bidentate nitrate species. Meanwhile, a new –NCO peak appeared at 2229 cm⁻¹, and its intensity increased and then decreased with the time. This indicates that the nitrate species is highly active to react with C₂H₅OH + O₂ to form –NCO species. On the other hand, when the nitrate species was completely consumed, a large amount of enolic species and acetate species became the dominant surface species over Ag/Al₂O₃.

The same experiment was also carried out using CH₃OCH₃ as the reductant, and the dynamic changes of in situ DRIFTS spectra as a function of time in a flow of CH₃OCH₃ + O₂ are presented in Fig. 5(b). After the feed gas was switched from NO + O₂ to CH₃OCH₃ + O₂, a large amount of nitrate species and formate species still remained on the Ag/Al₂O₃ catalyst,
indicating that the nitrate species has a low reactivity toward CH$_3$OCH$_3$ + O$_2$ to form –NCO species. This result again confirms that C$_2$H$_5$OH has a higher reactivity than CH$_3$OCH$_3$ during the SCR of NO$_x$ over Ag/Al$_2$O$_3$.

$$\text{NO + O}_2 + \text{C}_2\text{H}_5\text{OH} \rightarrow (\text{RCH=CH-O})\text{M}^+ + \text{NO} + \text{O}_2 \rightarrow \text{M-NCO} + \text{NO} + \text{O}_2 \rightarrow \text{N}_2$$  \hspace{1cm} (1)

$$\text{NO + O}_2 + \text{CH}_3\text{OCH}_3 \rightarrow (\text{HCOO})\text{M}^+ + \text{NO} + \text{O}_2 \rightarrow \text{M-NCO} + \text{NO} + \text{O}_2 \rightarrow \text{N}_2$$  \hspace{1cm} (2)

The enolic species and nitrate species formed from partial oxidation and adsorption of NO and C$_2$H$_5$OH over the catalyst, respectively, have a high reactivity to react with each other to form –NCO species, thus resulting in high NO reduction by C$_2$H$_5$OH. However, formate species and nitrate species formed from partial oxidation and adsorption of NO and CH$_3$OCH$_3$ over the catalyst have a low reactivity to react with each other to form –NCO species, and this results in the poor reduction of NO by CH$_3$OCH$_3$ over Ag/Al$_2$O$_3$.

3 Conclusions

The SCR of NO$_x$ over Ag/Al$_2$O$_3$ by C$_2$H$_5$OH and CH$_3$OCH$_3$ follows different reaction mechanisms. As the enolic species from C$_2$H$_5$OH has much higher reactivity toward NO + O$_2$ to form –NCO species (a major intermediate of the SCR of NO$_x$ with high activity) compared with the formate species from CH$_3$OCH$_3$ over Ag/Al$_2$O$_3$, C$_2$H$_5$OH is more effective than CH$_3$OCH$_3$ for the NO$_x$ reduction over Ag/Al$_2$O$_3$.
