Abstract

To further understand the role of substrates on the heterogeneous reactions of polycyclic aromatic hydrocarbons, the reactions of ozone with anthracene adsorbed on different mineral oxides (SiO$_2$, α-Al$_2$O$_3$ and α-Fe$_2$O$_3$) and on Teflon disc were investigated in dark at 20 °C. No reaction between ozone and anthracene on Teflon disc was observed when the ozone concentration was ~1.18 × 10$^{14}$ molecules cm$^{-2}$. The reactions on mineral oxides exhibited pseudo-first-order kinetics for anthracene loss, and the pseudo-first-order rate constant ($k_{1,\text{ads}}$) displayed a Langmuir–Hinshelwood dependence on the gas-phase ozone concentration. The adsorption equilibrium constants for ozone ($K_{O3}$) on SiO$_2$-1, SiO$_2$-2, α-Al$_2$O$_3$ and α-Fe$_2$O$_3$ were (0.81 ± 0.26) × 10$^{-15}$ cm$^3$, (2.83 ± 1.17) × 10$^{-15}$ cm$^3$, (2.48 ± 0.77) × 10$^{-15}$cm$^3$ and (1.66 ± 0.45) × 10$^{-15}$cm$^3$, respectively; and the maximum pseudo-first-order rate constant ($k_{1,\text{max}}$) on these oxides were (0.385 ± 0.058) s$^{-1}$, (0.101 ± 0.0138) s$^{-1}$, (0.0676 ± 0.0086) s$^{-1}$ and (0.0457 ± 0.004) s$^{-1}$, respectively. Anthraquinone was identified as the main surface product of anthracene reacted with ozone. Comparison with previous research and the results obtained in this study suggest that the reactivity of anthracene with ozone and the lifetimes of anthracene adsorbed on mineral dust in the atmosphere are determined by the nature of the substrate.

1. Introduction

Polycyclic aromatic hydrocarbons (PAHs), which mainly originate from the incomplete combustion of fossil fuels (petroleum, natural gas and coal) and biomass burning, have attracted much attention due to their allergenic, mutagenic, and carcinogenic properties (Finlayson-Pitts and Pitts, 1997). The global emission of atmospheric PAHs is roughly estimated to be 0.001 TgC yr$^{-1}$ and about 90% of PAHs emissions are anthropogenic (Calvert et al., 1984; Pöschl et al., 2001). Once emitted into the atmosphere, PAHs are able to partition between the gas-phase and atmospheric particulate matter. For example, semivolatile (3–4 rings) PAHs and those with lower volatility (more than 4 rings) are frequently found adsorbed on particulate matter, especially on particles lower than 5 μm in size (Pierce and Katz, 1975).

Due to interactions with atmospheric radicals and oxidants, such as OH, O$_3$, H$_2$O$_2$, HNO$_3$, and NO$_x$, PAHs may undergo homogeneous or heterogeneous reactions during its atmospheric residence time. Recently, modeling and laboratory studies have shown that heterogeneous reactions may be the dominant reactive loss process of atmospheric PAHs (Kwamena et al., 2007a; Miet et al., 2009). Heterogeneous reactions not only control the atmospheric fate and lifetime of adsorbed PAHs but also alter the physicochemical properties of particulate matter. Additionally, the products of the reaction (nitro-PAHs, oxy-PAHs) have been shown to be more carcinogenic or mutagenic (Pitts et al., 1978; Calvert et al., 2002). Field observations have found that atmospheric PAH concentration measured using conventional samplers without an ozone trap can underestimate the PAH concentration by more than 67% (Goriaux et al., 2006) or 50% (Schauer et al., 2003). Therefore, heterogeneous reactions between atmospheric oxidants and adsorbed PAHs attracted considerable interest over the past several decades (Pitts et al., 1978; Wu et al., 1984; Pöschl et al., 2001; Mmereki and Donaldson, 2003; Mmereki et al., 2004; Kahan et al., 2006; Kwamena et al., 2004, 2006, 2007a,b; Gloaguen et al., 2006; Perraudin et al., 2007a,b; Miet et al., 2009; Shiraïwa et al., 2009; Bedjanian et al., 2010; Bedjanian and Nguyen, 2010).

Anthracene is often used as a model PAH and its reaction with O$_3$ on various substrates has been widely investigated. Most previous studies on the heterogeneous reactions of PAHs have focused on carbonaceous aerosols (Pöschl et al., 2001; Kahan et al., 2006; Kwamena et al., 2004, 2007b). Anthraquinone was identified as the main product of anthracene ozonation on different substrates (Mmereki et al., 2004; Gloaguen et al., 2006; Kwamena et al., 2006; Perraudin et al., 2007b). These results suggest that the nature of the substrate greatly influences the heterogeneous reactivity of O$_3$ with PAHs adsorbed on carbonaceous aerosols.
On the other hand, recent field measurements have found that the concentration of PAHs (sum of 16 EPA list PAHs) ranges from 1.0 to 85.5 \( \mu \text{g} \cdot \text{g}^{-1} \) in the dustfall collected in Tianjin (Wu et al., 2005), and from 0.18 to 3.52 \( \mu \text{g} \cdot \text{g}^{-1} \) in the sandstorm depositions in Beijing (Fu et al., 2009). This indicates that mineral dust can adsorb PAHs in the real atmospheric particulate matter. Mineral dust, which mainly originates from arid and semi-arid regions with global source strength of about 1000–3000 Tg yr\(^{-1}\) (Dentener et al., 1996), is one of the most important contributors to the loading of atmospheric particulate matter. Therefore, it is very significant to investigate the chemical behavior of PAHs on mineral dust. The reaction between O\(_3\) and anthracene on silica was investigated in the literature (Alebić-Juretić et al., 1990; Perraudin et al., 2007a,b). Besides SiO\(_2\), other oxides including \( \alpha\)-Al\(_2\)O\(_3\) and \( \alpha\)-Fe\(_2\)O\(_3\) were also regarded as the main constituents of mineral dust (Usher et al., 2003; He et al., 2005). However, kinetic parameters were unavailable for the heterogeneous reactions of PAHs with O\(_3\) on \( \alpha\)-Al\(_2\)O\(_3\) and \( \alpha\)-Fe\(_2\)O\(_3\). In addition, to our knowledge, it is unknown that how the mineral dust affects the heterogeneous reactions of PAHs with O\(_3\).

To understand how the heterogeneous reactions of PAHs with O\(_3\) proceed, it is important to determine the surface reaction mechanism. However, it is controversial in literatures about the surface reaction mechanism of PAHs on different substrates. For example, Perraudin et al. (2007a) reported that the heterogeneous reactions of O\(_3\) with PAHs on graphite and silica accords with an Eley–Rideal gas–surface reaction mechanism, signifying a linear dependence of the apparent first-order rate constants with gas-phase O\(_3\) concentration. In contrast, a Langmuir–Hinshelwood reaction mechanism has been observed on phenylsiloxane oil (Kwamen et al., 2007b), soot (Pöschl et al., 2001), azelaic acid aerosols (Kwamen et al., 2004), octanol and decanol (Kahan et al., 2006), pyrex glass (Kwamen et al., 2006) and different coated aqueous surfaces (Mmereki et al., 2004), whereby the apparent first-order rate constants become independent of the O\(_3\) concentration when saturation of the surface occurs at high gas–phase O\(_3\) concentration.

According to the main composition of authentic mineral dust (He et al., 2005) and the upper continental crust (Usher et al., 2003), SiO\(_2\), Al\(_2\)O\(_3\) and Fe\(_2\)O\(_3\) were chosen as model oxides for atmospheric particles in Beijing. In this study, the heterogeneous reactions between O\(_3\) and anthracene adsorbed on mineral oxides including SiO\(_2\), \( \alpha\)-Al\(_2\)O\(_3\) and \( \alpha\)-Fe\(_2\)O\(_3\) were investigated. The surface reaction mechanism and the effect of mineral substrates on the reaction kinetics were studied in detail. The results will help for understanding the chemical behavior of PAHs in the atmosphere.

2. Experimental

2.1. Particles and characterization

The SiO\(_2\)-1 sample was purchased from Degussa (304N). The SiO\(_2\)-2 sample was prepared from SiO\(_2\)-1 by calcining at 1000 °C for 3 h. The \( \alpha\)-Fe\(_2\)O\(_3\) sample was supplied by Beijing Nanshangle Chemicals Factory. The \( \alpha\)-Al\(_2\)O\(_3\) sample was prepared from Boehmite (AIOOH, Shandong aluminium Corporation) by calcining at 1200 °C for 3 h. The specific surface area of these samples was measured using Nitrogen Brunauer–Emmett–Teller (BET) physisorption (Micromeritics ASAP 2000). The crystalline for these samples were identified as amorphous, hematite and corundum by a D/max-RL automatic powder X-ray diffractometer (XRD) using Cu K\( \alpha \) irradiation.

2.2. O\(_3\) generation and detection

O\(_3\) was generated by a homemade quartz O\(_3\) generator, in which a mixed flow of dry O\(_2\) and N\(_2\) was irradiated by a mercury lamp with wavelength of 185 and 254 nm. The concentration of O\(_3\) in the feed gas was controlled by varying the ratio of O\(_2\) to N\(_2\) passing through the mercury lamp and was detected by an O\(_3\) monitor (Model 202, 2B Technology). The O\(_3\) concentrations were from 0 to 2.44 \( \times \) 10\(^{15}\) molecules cm\(^{-3}\) (0–99 ppm).

2.3. Sample preparation and storage

Before adsorption of PAHs, mineral oxides were cleaned three times by ultrasonication in dichloromethane (Chromatographic Grade), followed by drying at room temperature. The concentration of PAHs in the extract of cleaned particles and the pure solvent were confirmed to be lower than the detection limit of the gas chromatography–mass spectrometer (Agilent 6890/5973).

Anthracene was adsorbed on particles by the impregnation method. (1.0 ± 0.0001) g of the cleaned particles was added into (20.0 ± 0.5) ml of n-hexane (Chromatographic Grade) containing (500 ± 10) \( \mu \text{g} \) of anthracene. After stirred homogeneously, the solvent was slowly evaporated using a rotary evaporator at 30 °C. Finally, the particles were dried at room temperature for 4 h. To avoid the photodegradation of the adsorbed PAHs, all particles in the amber glass flasks were stored at −18 °C in dark.

2.4. Reaction procedure and analytical methods

This kinetic study was performed in the dark at 20 °C. The (20.0 ± 0.1) mg of coated particles were evenly deposited on a Teflon disc (the geometric surface area is 3.39 cm\(^2\)), which was then placed in a quartz reactor. In the case of reaction on Teflon disc, (10 ± 0.2) \( \mu \text{g} \) of anthracene dissolved in CH\(_2\)Cl\(_2\) was evenly distributed on the disc. Before O\(_3\) was introduced into the quartz reactor, O\(_3\)/O\(_2\)/N\(_2\) of a given concentration was flowed through another blank reactor. When the concentration of O\(_3\) was stable, the feed gas was switched to the reactor containing adsorbed PAHs for reaction.

The reacted particle samples were ultrasonically extracted using (20.0 ± 0.5) ml CH\(_2\)Cl\(_2\) and were then filtered using a glass fibre filter, which had been previously cleaned in the same manner as the pure mineral oxides. Subsequently, CH\(_2\)Cl\(_2\) was evaporated and changed to (1.00 ± 0.01) ml n-hexane under a gentle stream of nitrogen gas at 20 °C.

Analyses of PAHs samples were performed by a GC–MS. The column was an HP 5MS (30 m, 0.25 mm i.d., 0.25 \( \mu \text{m} \) film thickness). The methodology for the analysis of PAHs is similar to the study carried out by Perraudin et al. (2007b). 1.0 \( \mu \text{l} \) of each sample was introduced via EPC splitless mode injection. The injector temperature was 280 °C. The oven temperature was held at 90 °C for 2 min, then increased from 90 °C to 330 °C at a rate of 10 °C min\(^{-1}\) and held at 330 °C for 5 min. Helium was used as carrier gas at a constant flow of 1.5 ml min\(^{-1}\). The interface temperature was kept at 280 °C during analysis. For identification of the product, mass detection was performed in the scan mode (mass/charge ratio ranging from 50 to 500 a.u), while for quantification of the reactant, mass detection was performed in selected ion monitoring (SIM) mode (dwell time = 10 ms, number of cycles per second = 12.3). The \( m/z \) ratio of 178 was used for quantification ion and the \( m/z \) ratio of 177 and 176 were used for confirmation ion for anthracene, respectively. The concentration of PAHs in solution were measured based on an external standard and the use of a calibration curve. The recovery obtained from spike and recovery experiments for anthracene on SiO\(_2\)-1, SiO\(_2\)-2, \( \alpha\)-Al\(_2\)O\(_3\) and \( \alpha\)-Fe\(_2\)O\(_3\) was (84.5 ± 9.31)%, (95.6 ± 3.51)%, (104 ± 4.31)%, and (106 ± 7.98)%, respectively. Therefore, GCMS areas were corrected for 100% recovery before quantification with the calibration curve.
2.5. Chemicals

All chemicals were chromatographic grade and used without further purification. CH2Cl2 and n-hexane were obtained from Baker Analyzed and Dima Technology Inc. Anthracene (99%) and anthraquinone (99.5%) were purchased from Acros Organics and Dr. Ehrenstorfer GmbH. Polynuclear aromatic hydrocarbon mix (the purity of anthracene is 100% and the prepared and certified analyte concentration of anthracene is 100 and 100.3 μg mL−1, respectively), which was used as the standard for calibrations, was purchased from AccuStandard, Inc. High purity N2 and O2 were supplied by Beijing AP BEIFEN Gases Inc.

3. Results and discussion

3.1. Characteristics of mineral oxides and surface coverage (%) of anthracene

Table 1 shows the specific surface area of various substrates and the surface coverage (%) of anthracene used in experiments. PAH surface coverage was calculated by assuming that no aggregates were formed during the coating and that PAH molecules were uniformly adsorbed on the substrates. Surface coverage was calculated by assuming that no aggregates were formed during the coating and that PAH molecules were uniformly adsorbed on the substrates. The cross section of anthracene molecule was assumed to be 1 nm2. Previous studies have shown that the reaction rate is faster when the surface coverage is below one monolayer of PAHs rather than above (Pöschl et al., 2001; Wu et al., 1984, 2005). However, there is no effect of PAHs fractional surface coverage on the kinetics in the submonolayer regime (Pöschl et al., 2001; Kwamena et al., 2004). Therefore, in order to eliminate the effect of anthracene coverage on reactivity, as shown in Table 1, the surface coverage of anthracene on all oxides was kept in the submonolayer regime.

3.2. Degradation kinetics of O3 and anthracene adsorbed on various substrates

In order to clarify that no compound vaporization was occurring during the reaction time, prior to the study of O3 react with anthracene, the blank experiments were performed under the same conditions as those used for the oxidation reactions but without O3. The results show that vaporization of anthracene was negligible under our experimental conditions (see Fig. 1). The kinetics data on various substrates were determined by monitoring the loss of anthracene concentration as a function of O3 exposure time, prior to the study of O3 react with anthracene. They suggest that the reactions are reasonably described by pseudo-first-order kinetics. Therefore, the experimental data were fitted using pseudo-first-order exponential functions, as shown in equation (1) (Perraudin et al., 2007a)

\[
\frac{[PAH]_i}{[PAH]_0} = \frac{[PAH]_{plateau} - [PAH]_{plateau}}{[PAH]_0} \times \exp\left(-k_{1,obs} \times t\right)
\]

where \([PAH]_i\) is the concentration of adsorbed PAH at a given time, \([PAH]_0\) is the initial concentration of adsorbed PAH, \([PAH]_{plateau}\) is the concentration of adsorbed PAH at the plateau (Fig. 2), and \(k_{1,obs}\) is the apparent rate constant of the pseudo-first-order reaction.

The \(k_{1,obs}\) were calculated to be \((1.67 \pm 0.22) \times 10^{-2}\), \((1.66 \pm 0.34) \times 10^{-2}\), \((1.16 \pm 0.42) \times 10^{-2}\) and \((0.86 \pm 0.31) \times 10^{-2}\) s\(^{-1}\) on SiO\(_2\)-1, SiO\(_2\)-2, α-Al\(_2\)O\(_3\) and α-Fe\(_2\)O\(_3\), respectively. Perraudin et al. (2007a) studied the reactions of O3 with anthracene on various silicas. Under similar concentration of O3 and initial surface coverage of anthracene, they measured the rate constants to be from \(0.9 \times 10^{-2}\) to \(1.8 \times 10^{-2}\) s\(^{-1}\). The rate constants on silica measured in this study were higher than those on other substrates, which may be due to the different surface properties and the presence of other functional groups on the silica surface.

Table 1 Characteristics of mineral oxides and surface coverage of anthracene.
are in good agreement with their results within experimental uncertainties. The fraction of unreacted anthracene was about 20%, 30%, 30% and 55% on SiO$_2$-1, SiO$_2$-2, α-Al$_2$O$_3$ and α-Fe$_2$O$_3$, respectively. The plateau shown in Fig. 2 was related to the specific surface area of the particle sample. SiO$_2$-1 with the largest specific surface area has the lowest plateau. Perraudin et al. (2007a) also reported that the degradation of PAHs reached a plateau on silica and the plateau was dependent on the specific surface area of particle samples. Kwamena et al. (2006) observed unreacted anthracene at both high and low anthracene surface coverage, which suggested that the anthracene was not being deposited as a smooth, uniform layer, but more likely as clumps or islands under their conditions even in a monolayer regime. Therefore, similar to the phenomenon reported by Perraudin et al. (2007a) and Kwamena et al. (2006), the plateau observed in this study was corresponded to a complex gas–solid reaction, which depended upon both the extent of PAH multilayering and the extent to which oxidized species hindered the oxidation of the surface material. The apparent rate constants of the reaction of O$_3$ reacted with anthracene adsorbed on SiO$_2$-1 and SiO$_2$-2 were the same within the experimental precision of the current method, illustrating that the surface coverage under one monolayer has no influence on the reaction between O$_3$ and anthracene when the concentration of O$_3$ was (1.18 ± 0.02) × 10$^{14}$ molecules cm$^{-2}$. As mentioned above, Kwamena et al. (2004) also found that the rate constants were not affected by the surface coverage in the monolayer regime. The SiO$_2$-2 and α-Al$_2$O$_3$ have similar specific surface areas, but the reaction on SiO$_2$-2 was faster than that on α-Al$_2$O$_3$. Thus, the difference of $k_{1,\text{obs}}$ on SiO$_2$, α-Al$_2$O$_3$ and α-Fe$_2$O$_3$ was due to the effect of the nature of substrate.

### 3.3. Degradation mechanism of O$_3$ and anthracene adsorbed on various substrates

In order to clarify the surface reaction mechanism of O$_3$ with anthracene adsorbed on these substrates, the $k_{1,\text{obs}}$ at different gas-phase O$_3$ concentrations were measured. As shown in Fig. 3, the plot of $k_{1,\text{obs}}$ is nonlinearity related to gas-phase O$_3$ concentration, which is consistent with the Langmuir–Hinshelwood reaction mechanism. This mechanism involves two species in which one reactant (i.e. the PAHs) is adsorbed on the particle surface while a second reactant (i.e. O$_3$) is in equilibrium between the gas phase and the surface. The surface reaction takes place between two adsorbed species on the surface of the substrates. This kind of mechanism was observed for the reaction between surface-bound PAHs and O$_3$ on various substrates (Pöschl et al., 2001; Kahan et al., 2006; Kwamena et al., 2004, 2006, 2007b; Mmereki et al., 2004).

The principles of the Langmuir–Hinshelwood model are similar to the Langmuir adsorption isotherm, assuming that the adsorption of the gas-phase species cannot proceed beyond monolayer coverage. Therefore, there are a limited number of sites for O$_3$ adsorption. When the surface is saturated at high gas-phase O$_3$ concentration, the rate of the reaction should become independent of the O$_3$ concentration.

In the Langmuir–Hinshelwood mechanism, the $k_{1,\text{obs}}$ can be interpreted as (Pöschl et al., 2001, 2007; Mmereki and Donaldson, 2003; Mmereki et al., 2004; Kahan et al., 2006; Kwamena et al., 2004, 2006, 2007b)

$$k_{1,\text{obs}} = \frac{k_2[\text{SS}]K_{20}[\text{O}_3]_g}{I + K_{20}[\text{O}_3]_g}$$

(2)

where [SS]$_g$ is the surface concentration of ozone adsorption sites, $K_{20}$ is the Langmuir adsorption equilibrium constant for O$_3$, i.e. the ratio of rate constants between the adsorption and desorption of O$_3$ ($k_{0,3}/k_{0,3}$), [O$_3$]$_g$ is the gas-phase concentration of O$_3$. From this equation, it is evident that $k_{1,\text{obs}}$ is dependent on both the number of surface sites and the gas-phase species concentration of O$_3$. The $K_2$[SS]$_g$ represents the maximum pseudo-first-order rate constant of anthracene at high O$_3$ concentration ($\theta_{O_3} = 1$), and is replaced with $k_{1,\text{max}}$. Then equation (2) can be modified as (Kwamena et al., 2004, 2006, 2007b)

$$k_{1,\text{obs}} = k_{1,\text{max}}K_{20}[\text{O}_3]_g$$

(3)

Fig. 3 shows the fitting curves based on equation (3) using nonlinear least-squares fitting. The fitting parameters, including $K_0$, and $k_{1,\text{max}}$ are listed in Table 2. The errors for these parameters were obtained from the statistical errors of the nonlinear least-squares fitting.

As can be seen in Fig. 3, the reactions between O$_3$ and anthracene adsorbed on SiO$_2$-1, SiO$_2$-2, α-Al$_2$O$_3$, and α-Fe$_2$O$_3$ are in accordance with the Langmuir–Hinshelwood mechanism. The correlation coefficients were 0.989, 0.985, 0.984, and 0.994, respectively. Although most previous studies have provided evidence that the Langmuir–Hinshelwood is a general mechanism in the reaction of O$_3$ and surface-adsorbed anthracene (Mmereki and Donaldson, 2003; Mmereki et al., 2004; Kahan et al., 2006; Kwamena et al., 2006, 2007b), an Eley–Rideal reaction mechanism was observed for the reaction between O$_3$ and PAHs on SiO$_2$ in the studies by Perraudin et al. (2007a), Miet et al. (2009), Alebić-Juretić et al. (1990) and Wu et al. (1984). However, the ozone concentrations in previous studies fall within the linear regime of this study. A Langmuir–Hinshelwood reaction mechanism should have been observed if these studies had been carried out over a larger O$_3$ concentration range.

The fitting parameters ($K_0$ and $k_{1,\text{max}}$) for the reactions between O$_3$ and anthracene adsorbed on various substrates are summarized along with literature results in Table 2. The $K_0$ values range from 0.81 × 10$^{-15}$ cm$^3$ to 2.83 × 10$^{-15}$ cm$^3$ on SiO$_2$-1, SiO$_2$-2, α-Al$_2$O$_3$, and α-Fe$_2$O$_3$ in this study and range from 0.49 × 10$^{-15}$ cm$^3$ to 2.8 × 10$^{-15}$ cm$^3$ in the literature work except the reaction on phenylsiloxane oil. Kwamena et al. (2007b) compared the $K_0$ values on different substrates and proposed that O$_3$ prefers partitioning to nonpolar surfaces. Phenylsiloxane oil is nonpolar which contains many phenyl and methyl groups. Therefore, it has a much higher $K_0$ values. As shown in Table 2, the small value of $K_0$ on the surface of water suggests the strong polarity of water, and the middle values of $K_0$ on SiO$_2$-1, SiO$_2$-2, α-Al$_2$O$_3$, and α-Fe$_2$O$_3$ suggest the moderate polarity of these oxides.

The decomposition mechanism of O$_3$ on metal oxides is shown as follows (Li et al., 1998; Li and Oyama, 1998; Oyama, 2000):

$$\begin{align*}
O_3 + + &\rightarrow O_2^* + O_2 \\
O_3 + O_2^* &\rightarrow O_2 + O_2 + O_2 \\
O_2^* &\rightarrow + O_2
\end{align*}$$

where the asterisk represents surface sites and O$_2^*$ is the peroxide species. It means O$_3$ can catalytically decompose into surface O atom and molecular O$_2$. However, as proposed by Kwamena et al. (2006), Mmereki et al. (2004) and Perraudin et al. (2007b), ozonation of surface-bound anthracene involves the addition reaction between molecular ozone and the 9- and 10-C positions of anthracene via an ozone intermediate. This was well supported by that 9,10-anthraquinone was found as the major product on the mineral oxides (Fig. 5). Therefore, the decomposition of O$_3$ by metal oxide should slow down the rate of anthracene degradation on the mineral oxide by decreasing the surface concentration of molecular ozone. Thus, it can be speculated that the metal oxide with higher catalytic activity for O$_3$ decomposition should show lower degradation rate of anthracene by O$_3$. 

---

The text is a scientific discussion on the degradation of anthracene and ozone adsorbed on various substrates. It covers the reaction mechanisms, fitting parameters, and the decomposition process of ozone on metal oxides.
In order to further explain the effect of O3 decomposition on these reactions, the magnitude of the decomposition rate of O3 on mineral oxides \(K_{h; O3}\) was estimated. Because we cannot directly measure the \(k\) or \(g\) of ozone on these oxides, \(K_{h; O3}\) was estimated based on the mass-independent steady-state reactive uptake coefficient of O3 on these three mineral oxides (0 on SiO2, 7.6 × 10^−6 on \(\alpha\)-Al2O3 and 2.2 × 10^−5 on \(\alpha\)-Fe2O3, respectively) reported by Michel et al. (2003) and the specific surface area of these mineral oxides in this study. The value of \(K_{h; O3}\) were calculated according to (Ravishankara, 1997)

\[
k = \frac{v_{O3} A \gamma}{4}
\]

where \(A\) is the surface area for reactions in square centimeters per cubic centimeter of air, \(v\) is the mean molecular speed of ozone molecules given by \(\frac{8RT}{\pi M_{O3}}\) \(\frac{1}{2}\), where \(R\) stands for the gas constant, \(T\) is the absolute temperature and \(M_{O3}\) is the molar mass of ozone \((v_{O3} = 3.62 \times 10^4 \text{ cm s}^{-1} \text{ at } 298 \text{ K})\) and \(\gamma\) is the uptake coefficient of ozone on mineral oxides. The value of \(A\) was calculated according to

![Fig. 3. Pseudo-first-order rate constants \(k_{act}\) as a function of gas-phase O3 concentration for the reactions of O3 and anthracene adsorbed on (A) SiO2-1, (B) SiO2-2, (C) \(\alpha\)-Al2O3 and (D) \(\alpha\)-Fe2O3. The error bars represent the standard error of the corresponding anthracene decay plots (±1 s.e.).](image)

### Table 2

Comparison of kinetic parameters and lifetimes for the reaction of ozone with anthracene adsorbed on various substrates.

* These data were converted from A and B parameters used by Kahan et al. (2006) and Mmereki et al. (2004).

As effective for the reaction during reaction time. Because the amount of the sample for reaction is only 0, 0, 2.69 ppm ozone in the literature (Michel et al., 2003), however, the concentration of ozone used in this work was in a range of 1011–1012 molecules cm⁻³. The interaction between anthracene molecules and the substrate through k₁ also plays an important role in the reaction between anthracene and ozone. Therefore, the reactivity of anthracene adsorbed on mineral dust with O₃ is determined by the nature of the substrate (kmax). On the other hand, the migrations of surface-adsorbed anthracene via desorption/adsorption may play a role in the micro-interfacial process of the heterogeneous reaction. The interaction between anthracene molecules and the substrate need to be further studied in the future works.

In order to evaluate the contribution of heterogeneous reactions of PAHs with O₃ to the loss of ozone in the troposphere, the uptake coefficient (γ) of O₃ was calculated based on the pseudo-first-order rate constant, as mentioned above. The uptake coefficient is the ratio of the number of collisions that result in a reaction to the total number of collisions between a gas-phase molecule and a surface. For a simple bimolecular reaction mechanism, the uptake coefficient is calculated as follows (Ravishankara, 1997)

$$\gamma = \frac{4k_{1, obs}}{\sigma_{ANT}e_{O_3}\rho_{O_3}}$$

where σANT represents the collision cross section of the anthracene molecule and ρ is the mean thermal velocity of O₃. However, this equation must be modified with equation (3) when the reaction is described by the Langmuir–Hinshelwood model (Ammann et al., 2003; Pöschl et al., 2007)

$$\gamma = \frac{4k_{1, max}K_{O_3}}{\sigma_{ANT}e_{O_3} \left(1 + K_{O_3}e_{O_3}\right)}$$

The uptake coefficients of O₃ on anthracene at different O₃ concentration are obtained based on the k₁,obs measured in this work according to equation (7) and shown in Fig. 4. The error of the uptake coefficients was taken as the standard error of k₁,obs. The curve illustrates a trend of decreasing of uptake coefficient with increasing of O₃ concentration, which was obtained from a nonlinear least-squares fit according to equation (7). In other studies, the reactions of O₃ and PAHs adsorbed on soil, azaalic acid aerosol and the air–aqueous interface have also exhibited a similar trend between uptake coefficients and O₃ concentrations (Pöschl et al., 2001; Mmereki and Donaldson, 2003; Kwamena et al., 2004). This trend is attributed to more ineffective collisions between gas-phase O₃ and the particle surface at higher O₃ concentrations when the O₃ surface coverage was saturated (Kwamena et al., 2004). The maximum values (when O₃ concentration is approaching zero) of the apparent uptake coefficient were 4.07 × 10⁻⁴ on SiO₂-1, 2.64 × 10⁻⁴ on SiO₂-2, 1.47 × 10⁻⁴ on α-Al₂O₃, and 2.64 × 10⁻⁴ on α-Fe₂O₃.
and $1.03 \times 10^{-4}$ on $\alpha$-Fe$_2$O$_3$. The maximum uptake coefficient of ozone on anthracene was close to the initial reactive uptake coefficients of O$_3$ on SiO$_2$, $\alpha$-Al$_2$O$_3$ and $\alpha$-Fe$_2$O$_3$ measured by Michel et al. (2003). Because the uptake of O$_3$ by anthracene is small and the concentration of anthracene in the atmosphere is trace, the contribution of heterogeneous reactions of PAHs with O$_3$ to the loss of ozone in the troposphere can be ignored. The uptake coefficients of O$_3$ measured in this work were higher than the values reported for O$_3$ reaction with benzo[a]pyrene on soot (Pöschl et al., 2001) and azalaic acid (Kwamena et al., 2004). The uptake coefficients of O$_3$ were also higher than the values for O$_3$ reaction with anthracene at the air–aqueous interface (Mmereki and Donaldson, 2003). The results also suggest a strong effect of substrate on this reaction.

3.4. Products of anthracene degradation

The chromatogram of the particle extract was similar for the different mineral oxides. Fig. 5 shows a representative chromatogram of the extract from $\alpha$-Al$_2$O$_3$ on which anthracene reacted with O$_3$. On the basis of their unique EI mass spectra, three peaks in the chromatogram were identified as anthracene, anthrone and anthraquinone at retention times of 17.44, 19.56 and 19.92 min, respectively. Additionally, anthracene and anthraquinone were confirmed by the spectra of standard samples.

3.5. The lifetime of anthracene

The atmospheric lifetimes ($\tau$) of anthracene were calculated based on the rate constants according to equation (8) (Pflieger et al., 2009).

$$\tau = \frac{1}{k_{1, obs}}$$

(8)

and assuming that the heterogeneous reactions of O$_3$ with anthracene is the only degradation process occurring in the atmosphere. The values of $k_{1, obs}$ under different concentrations of O$_3$ (for the oxide substrates) were calculated using equation (5).

Because the difference of $k_{1, obs}$ (under a few ppb of O$_3$) between SiO$_2$-1 and SiO$_2$-2 was within the uncertainty, their average value was used to calculate the lifetime of anthracene on SiO$_2$. The lifetime of anthracene when reacting with O$_3$ on SiO$_2$, $\alpha$-Al$_2$O$_3$, and $\alpha$-Fe$_2$O$_3$ were calculated to be 4.66 min, 8.3 min and 18.2 min, respectively, in highly polluted areas ($[O_3] = 500$ ppb (Perreaud et al., 2007a)); and to be 1.51 h, 2.7 h and 5.96 h in clean areas ($[O_3] = 25$ ppb), respectively. Taking into account the results from previous studies (Table 2), the lifetime of anthracene ranged from 3 min on phenylsilsolane oil to approximately 51 h on hexanoic acid surfaces in highly polluted areas and from 0.48 h to approximately 42 days in clean areas, respectively. Considering that mineral dust is the largest contributor to particulate matter in the atmosphere, and that the reaction of O$_3$ with anthracene adsorbed on mineral dust was faster than that on organic particle surfaces, it highlights the importance of the nature of the support and suggests that these reactions are an important sink of PAHs in highly polluted regions.

4. Conclusions

In order to improve our understanding of how the aerosol substrate influences the heterogeneous reaction of ozone with anthracene, we systematically investigated the kinetic of the heterogeneous reaction of ozone with anthracene adsorbed on different mineral oxides (SiO$_2$, $\alpha$-Al$_2$O$_3$ and $\alpha$-Fe$_2$O$_3$). This work showed that the reactions between ozone and anthracene adsorbed on mineral oxides proceed by the Langmuir–Hinshelwood mechanism.

The lifetime of anthracene on SiO$_2$, $\alpha$-Al$_2$O$_3$ and $\alpha$-Fe$_2$O$_3$ due to reaction with O$_3$ were calculated to be 4.66 min, 8.3 min and 18.2 min, respectively, in highly polluted areas ($[O_3] = 500$ ppb); and to be 1.51 h, 2.7 h and 5.96 h in clean areas ($[O_3] = 25$ ppb), respectively. Compared to that on carbonaceous aerosols, the shorter lifetimes on mineral oxides suggest that these reactions may be an important sink for PAHs in highly polluted areas. Thus, mineral dust needs to be considered into accurate models for estimation the reactive fate of PAHs in the atmosphere.

Additionally, the difference among the rate constants and lifetimes of ozonization of anthracene on different oxides measured in this work showed that the nature of substrate has a strong influence on the heterogeneous reactions between ozone and anthracene. The oxide with higher decomposition rate constant of O$_3$ (such as $\alpha$-Fe$_2$O$_3$) showed a lower reactivity of anthracene. Thus, the substrate effect of oxides on the reactions between ozone and anthracene can be ascribed to the difference in the decomposition reactivity of O$_3$ on oxides. It should be pointed out that the nature mineral dust may have less catalytic effect to ozone decomposition, thus, the result must be carefully extrapolate to real atmosphere environment.
