**Abstract** Ag/Al<sub>2</sub>O<sub>3</sub> is a promising catalyst for the selective catalytic reduction (SCR) by hydrocarbons (HC) of NO<sub>x</sub> in both laboratory and diesel engine bench tests. New developments of the HC-SCR of NO<sub>x</sub> over a Ag/Al<sub>2</sub>O<sub>3</sub> catalyst are reviewed, including the efficiencies and sulfur tolerances of different Ag/Al<sub>2</sub>O<sub>3</sub>-reductant systems for the SCR of NO<sub>x</sub>; the low-temperature activity improvement of H<sub>2</sub>-assisted HC-SCR of NO<sub>x</sub> over Ag/Al<sub>2</sub>O<sub>3</sub>; and the application of a Ag/Al<sub>2</sub>O<sub>3</sub>-ethanol SCR system with a heavy-duty diesel engine. The discussions are focused on the reaction mechanisms of different Ag/Al<sub>2</sub>O<sub>3</sub>-reductant systems and H<sub>2</sub>-assisted HC-SCR of NO<sub>x</sub> over Ag/Al<sub>2</sub>O<sub>3</sub>. A SO<sub>2</sub>-resistant surface structure in situ synthesized on Ag/Al<sub>2</sub>O<sub>3</sub> by using ethanol as a reductant is proposed based on the study of the sulfate formation. These results provide new insight into the design of a high-efficiency NO<sub>x</sub> reduction system. The diesel engine bench test results showed that a Ag/Al<sub>2</sub>O<sub>3</sub>-ethanol system is promising for catalytic cleaning of NO<sub>x</sub> in diesel exhaust.

## 1 Introduction

Air pollution by nitrogen oxides (NO<sub>x</sub>) emitted from both mobile and stationary sources has become a serious

environmental problem because of the formation of acid rain and photochemical smog [1]. The three-way catalysts have been applied successfully to eliminate the NO<sub>x</sub> from the gasoline engines. Although the improvement of fuel economy and lower emissions of CO<sub>2</sub> can be obtained by using diesel and lean-burn gasoline engines, the oxygen rich exhausts make the conventional three-way catalysts unsuitable for the reduction of NO<sub>x</sub> emissions. As a highly promising technology, selective catalytic reduction (SCR) of NO<sub>x</sub> with various reductants has been extensively studied. Since unburned HC and CO in exhausts of diesel and lean-burn gasoline engines are not enough to reduce NO<sub>x</sub>, the additional reductant is needed. Besides the SCR of NO<sub>x</sub> by NH<sub>3</sub> or urea as a reductant, the SCR of NO<sub>x</sub> by hydrocarbon (HC) as a reductant can be a possible method to the removal of NO<sub>x</sub> from diesel and lean-burn gasoline engines. In recent studies, relatively durable and inexpensive alumina-supported silver catalysts (Ag/Al<sub>2</sub>O<sub>3</sub>) have been considered to be a promising candidate for practical usage in the HC-SCR of NO<sub>x</sub> [2–8]. In our research into the HC-SCR of NO<sub>x</sub> over Ag/Al<sub>2</sub>O<sub>3</sub>, we found a novel enolic surface species on Ag/Al<sub>2</sub>O<sub>3</sub> [9] and proposed a new mechanism to explain the high-level efficiency of the SCR of NO<sub>x</sub> by ethanol over Ag/Al<sub>2</sub>O<sub>3</sub> [7, 9, 10], as shown in Scheme 1. The reaction starts with the formation of nitrates adsorbed on Al<sub>2</sub>O<sub>3</sub> via NO oxidation by O<sub>2</sub>, and enolic species and acetate adsorbed on Ag and Al<sub>2</sub>O<sub>3</sub> via the partial oxidation of C<sub>2</sub>H<sub>5</sub>OH on Ag/Al<sub>2</sub>O<sub>3</sub> [7]. Subsequently, the enolic species can react with nitrates or NO + O<sub>2</sub> to form surface –NCO species adsorbed on Ag site (Ag–NCO) and Al site (Al–NCO) as a key intermediate directly, or via organo-nitrogen compounds (such as R-ONO and R-NO<sub>2</sub>) [11]. Finally, Ag–NCO and Al–NCO species react with NO + O<sub>2</sub> and nitrates to yield N<sub>2</sub>. It should be pointed

**Scheme 1** The mechanism of the SCR of NO<sub>x</sub> by C<sub>2</sub>H<sub>5</sub>OH over Ag/Al<sub>2</sub>O<sub>3</sub>

out that the enolic species, the main surface species during the partial oxidation of C<sub>2</sub>H<sub>5</sub>OH, has a higher reactivity with NO + O<sub>2</sub> to form surface –NCO species than acetate, which results in the high-level efficiency of NO<sub>x</sub> reduction over Ag/Al<sub>2</sub>O<sub>3</sub> by C<sub>2</sub>H<sub>5</sub>OH. Also, the role of the active phase Ag is to accelerate the formation of these above intermediates, and then these intermediates are finally transferred onto the support Al<sub>2</sub>O<sub>3</sub>. On the basis of these results, we concluded that C<sub>2+</sub> oxygenated hydrocarbons are more efficient than hydrocarbons as reductants for the SCR of NO<sub>x</sub>.

From a practical point of view, a catalyst used for the SCR of NO<sub>x</sub> should be resistant to both SO<sub>2</sub> and H<sub>2</sub>O in real exhaust gases; and the type of reductant is an important factor for the SO<sub>2</sub> and H<sub>2</sub>O tolerances of Ag/Al<sub>2</sub>O<sub>3</sub> during the SCR of NO<sub>x</sub>. Previous studies have shown that Ag/Al<sub>2</sub>O<sub>3</sub> was usually deactivated in the presence of SO<sub>2</sub> and H<sub>2</sub>O during the HC-SCR of NO<sub>x</sub> [12–16]. However, ethanol was extremely effective for the SCR of NO<sub>x</sub> over Ag/Al<sub>2</sub>O<sub>3</sub> even in the presence of H<sub>2</sub>O and SO<sub>2</sub>, which was confirmed by diesel engine bench tests [7, 17–19]. To achieve the practical use, a SCR catalyst should also have a high level of activity for NO<sub>x</sub> reduction at lower temperature, considering the typical temperatures of diesel exhausts and cold-start driving cycle. Modification of the reaction atmosphere by adding H<sub>2</sub> to an HC-SCR system could be useful because of the surprising promotional effect on the SCR of NO<sub>x</sub> over Ag/Al<sub>2</sub>O<sub>3</sub> catalyst [20–22].

In this review, we summarize our recent studies of: (1) the mechanistic difference of the SCR of NO<sub>x</sub> over Ag/Al<sub>2</sub>O<sub>3</sub> using different reductants; (2) the SO<sub>2</sub> tolerance of a Ag/Al<sub>2</sub>O<sub>3</sub>-reductant system; (3) the promotional effect and mechanism of H<sub>2</sub>-assisted HC-SCR of NO<sub>x</sub> over Ag/Al<sub>2</sub>O<sub>3</sub>; (4) application of a Ag/Al<sub>2</sub>O<sub>3</sub>-C<sub>2</sub>H<sub>5</sub>OH-SCR system with a heavy-duty diesel engine. These results provide new insight into the design of the high-efficiency NO<sub>x</sub> reduction system for practical use.

## 2 SCR of NO<sub>x</sub> with Various Oxygenated Hydrocarbon Reductants Over Ag/Al<sub>2</sub>O<sub>3</sub>

### 2.1 Reaction Activity of Various Oxygenated Hydrocarbon Reductants for the SCR of NO<sub>x</sub> Over a Ag/Al<sub>2</sub>O<sub>3</sub> Catalyst

The efficiencies of different Ag/Al<sub>2</sub>O<sub>3</sub>-reductant systems for the SCR of NO<sub>x</sub> were examined [23]. In the previous paper [7], the preparation of Ag/Al<sub>2</sub>O<sub>3</sub> was described in detail, and an optimum loading of Ag on Al<sub>2</sub>O<sub>3</sub> (around 4 wt.%) was confirmed. Therefore, the 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> catalyst was adopted in this review. The reductants used here were classified as: C1 (CH<sub>3</sub>OH, dimethyl ether (DME)), C2 (C<sub>2</sub>H<sub>5</sub>OH, CH<sub>3</sub>CHO), C3 (C<sub>3</sub>H<sub>6</sub>, isopropyl alcohol (IPA), 1-propanol and acetone) and C4 (1-butanol). Figure 1 shows the NO<sub>x</sub> conversions with various reductants over Ag/Al<sub>2</sub>O<sub>3</sub>. High-level conversions of NO<sub>x</sub> were achieved in the temperature range of 473–773 K when using C2, C3 and C4 reductants. In the case of C1 reductants, it is worth noting that the level of NO<sub>x</sub> conversion was much lower than those of using C2, C3 and C4 as reductants under the same conditions. The results indicate that conversion of NO<sub>x</sub> over Ag/Al<sub>2</sub>O<sub>3</sub> is influenced strongly by the reductants, and the efficiency order of the reductants for the SCR of NO<sub>x</sub> over Ag/Al<sub>2</sub>O<sub>3</sub> is proposed as follows: C4 ≈ C2 > C3 >> C1.

**Fig. 1** Activities of 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> for the SCR of NO<sub>x</sub> with various reductants. Conditions: NO, 800 ppm; O<sub>2</sub>, 10%; H<sub>2</sub>O, 10%; reductants (methanol 3,030 ppm or DME 3,030 ppm or ethanol 1,565 ppm or acetaldehyde 1,565 ppm or propene 1,714 ppm or IPA 1,043 ppm or 1-propanol 1,043 ppm or acetone 1,043 ppm or 1-butanol 783 ppm) in N<sub>2</sub> balance at a total flow rate of 2,000 cm<sup>3</sup>/min, GHSV = 50,000 h<sup>-1</sup>

## 2.2 Reaction Mechanism of the SCR of $\text{NO}_x$ by Various Reductants Over $\text{Ag}/\text{Al}_2\text{O}_3$

It is well known that the reaction mechanism of the SCR of  $\text{NO}_x$  depends mainly on the type of catalyst, the identity of reagents, the type of reductant, and the reaction conditions [24–27]. So far, researchers have agreed that the  $-\text{NCO}$  species acts as the key intermediate during the SCR of  $\text{NO}_x$ , and its high reactivity with  $\text{NO} + \text{O}_2$  results in a highly efficient reduction of  $\text{NO}_x$  [7, 9–11, 15, 16, 21, 28–31]. We recently proposed a novel mechanism for the SCR of  $\text{NO}_x$  by  $\text{C}_2\text{H}_5\text{OH}$ , as shown in Scheme 1, where the surface enolic species is related to the high surface concentration of  $-\text{NCO}$  and the high efficiency of  $\text{NO}_x$  reduction by  $\text{C}_2\text{H}_5\text{OH}$  [7, 9, 10]. In order to clarify the high activity of enolic species towards  $\text{NO} + \text{O}_2$  to form  $-\text{NCO}$ , the dynamic changes of the surface intermediates on  $\text{Ag}/\text{Al}_2\text{O}_3$  as a function of time have been investigated by using in situ DRIFTS measurement [10]. Figure 2 shows time dependence of the integrated area of the bands for different species in the DRIFTS spectra. A sharp decrease in the band due to enolic species was observed in a flow of  $\text{NO} + \text{O}_2$  on  $\text{Ag}/\text{Al}_2\text{O}_3$  after exposed to  $\text{C}_2\text{H}_5\text{OH} + \text{O}_2$ . The band assignable to enolic species sharply disappeared after 5 min with simultaneous formation of an  $-\text{NCO}$  band. Then band assignable to acetate slowly decrease after 5 min, showing the lower reactivity of acetate than enolic species. From the dynamic changes of these bands in a flow of  $\text{NO} + \text{O}_2$ , we conclude that enolic species on  $\text{Ag}/\text{Al}_2\text{O}_3$  are highly active towards  $\text{NO} + \text{O}_2$ , resulting in the formation of the  $-\text{NCO}$  species which is the key reaction intermediate in the SCR of  $\text{NO}_x$ . This mechanism has already explained rationally the difference in the SCR of

**Fig. 2** Time dependence of the integrated area of the bands in a flow of  $\text{NO} + \text{O}_2$  at 673 K. Before the measurement, the catalyst was pre-exposed to a flow of  $\text{C}_2\text{H}_5\text{OH} + \text{O}_2$  for 60 min at 673 K. Conditions:  $\text{NO}$ , 800 ppm;  $\text{C}_2\text{H}_5\text{OH}$ , 1,565 ppm;  $\text{O}_2$ , 10%

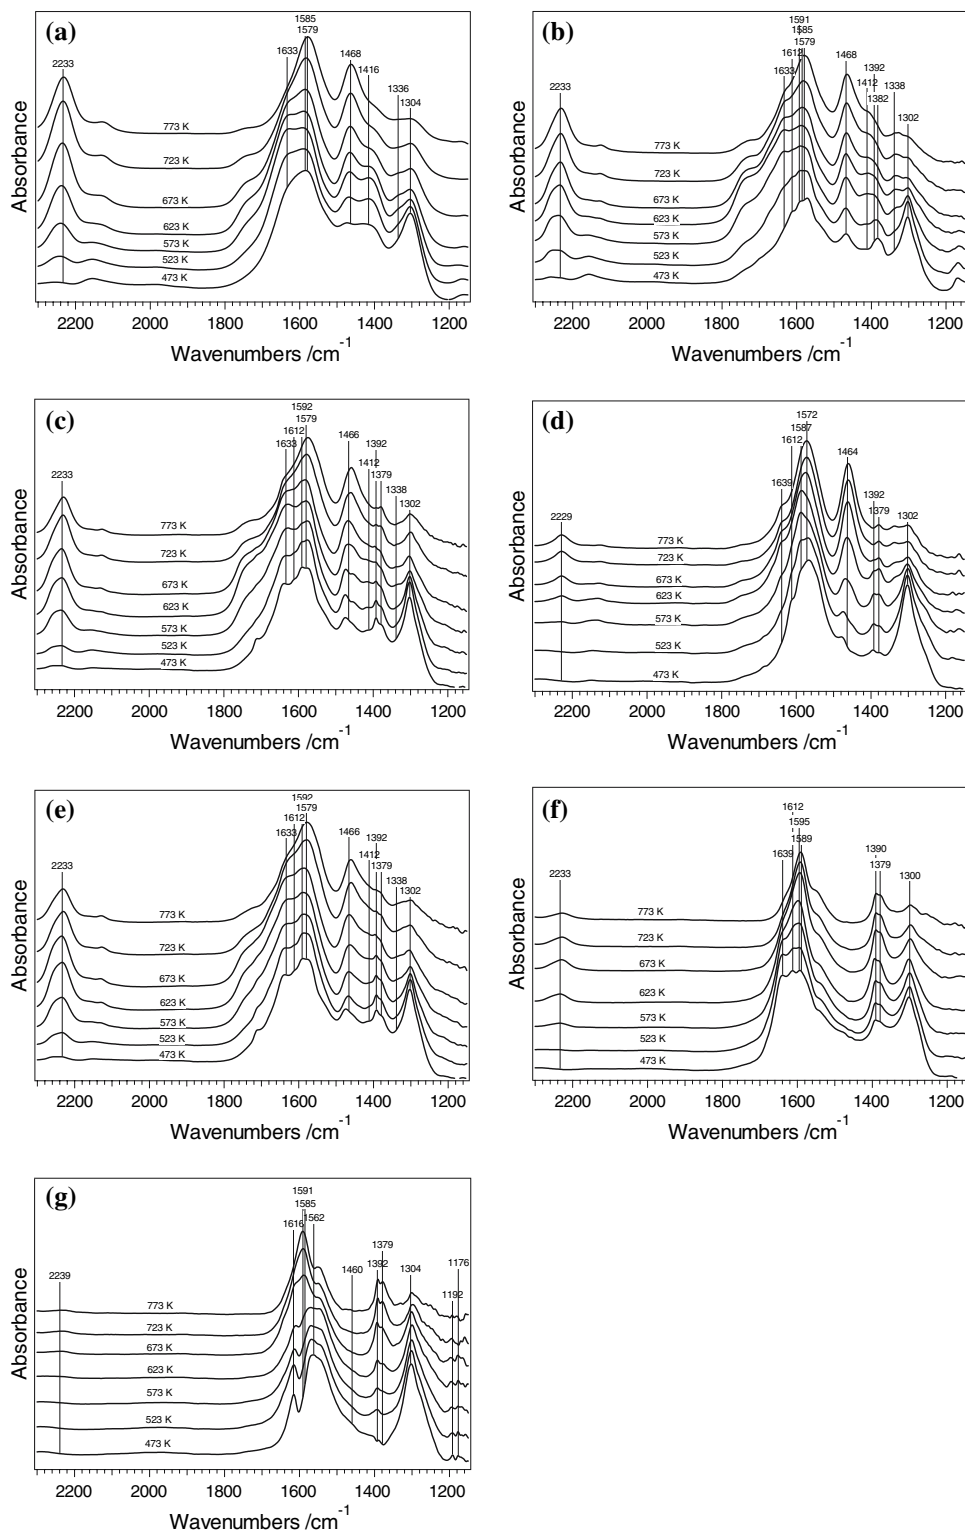

$\text{NO}_x$  when using  $\text{C}_2\text{H}_5\text{OH}$  and  $\text{C}_3\text{H}_6$  as reductants [10]. To obtain further theoretical information about the highly efficient catalyst–reductant system, it is very important to investigate the different reaction mechanisms of the SCR of  $\text{NO}_x$  with different reductants over  $\text{Ag}/\text{Al}_2\text{O}_3$ .

The difference between the above reductants for the SCR of  $\text{NO}_x$  over  $\text{Ag}/\text{Al}_2\text{O}_3$  was investigated by the in situ DRIFTS method. As shown in Fig. 3a–e, the very strong peak at around 2,229–2,233  $\text{cm}^{-1}$  is associated with the  $-\text{NCO}$  species adsorbed on Ag site of  $\text{Ag}/\text{Al}_2\text{O}_3$  catalyst, as observed in other  $\text{NO}_x/\text{O}_2$ /hydrocarbon reactions [7, 9–11, 15, 16, 21, 28–31]. The peaks around 1,633–1,639  $\text{cm}^{-1}$ , 1,412–1,416  $\text{cm}^{-1}$  and 1,336–1,338  $\text{cm}^{-1}$  are assigned to the surface enolic species derived from the partial oxidation of C2–C4 reductants over  $\text{Ag}/\text{Al}_2\text{O}_3$  [7, 9, 10, 23, 32]. The enolic species has a crucial role in the  $-\text{NCO}$  formation during the SCR of  $\text{NO}_x$  [7, 9, 10, 23]. In addition, the strong peaks around 1,572–1,579  $\text{cm}^{-1}$  and 1,464–1,468  $\text{cm}^{-1}$  are assigned to the acetate species, and the peaks around 1,585–1,589  $\text{cm}^{-1}$  and 1,300–1,304  $\text{cm}^{-1}$  are due to the nitrates adsorbed on  $\text{Ag}/\text{Al}_2\text{O}_3$  [7, 9, 10, 29–31]. The peaks around 1,591–1,595  $\text{cm}^{-1}$ , 1,379  $\text{cm}^{-1}$  and 1,390–1,392  $\text{cm}^{-1}$  are assigned to the surface formate species formed from the partial oxidation of C1 reductants over  $\text{Ag}/\text{Al}_2\text{O}_3$  (Fig. 3f and g) [23]. Based on the above results, we conclude that the formate species is main species in the partial oxidation of C1, while the enolic species is main species in the partial oxidation of C2–C4 reductants on the  $\text{Ag}/\text{Al}_2\text{O}_3$  surface. The assignments of the main IR bands are summarized in Table 1.

As can be seen in Fig. 3f and g, the formation of  $-\text{NCO}$  species in the  $\text{NO}_x/\text{O}_2/\text{C1}$  reductant reactions is different from those of the  $\text{NO}_x/\text{O}_2/\text{C2–C4}$  reductant reactions. Taking the relationship between the concentration of  $-\text{NCO}$  and efficiency of  $\text{NO}_x$  reduction, for C2–C4 reductants, the high concentration of  $-\text{NCO}$  species should account for the corresponding highly efficient  $\text{NO}_x$  reduction. In addition, we cannot observe an obvious difference among those figures (Fig. 3a–e), indicating that C2, C3 and C4 reductants are likely to follow a similar reaction mechanism during the SCR of  $\text{NO}_x$ . As for C1 reductants, a very weak band of  $-\text{NCO}$  species was observed under the same experimental conditions, which can well explain the relatively low efficiency of the SCR of  $\text{NO}_x$  (Fig. 3f and g).

We have proposed the mechanism of the SCR of  $\text{NO}_x$  with  $\text{C}_2\text{H}_5\text{OH}$  and IPA over  $\text{Ag}/\text{Al}_2\text{O}_3$ , where the surface enolic species was found to be related to the high surface concentration of  $-\text{NCO}$  and the high efficiency of  $\text{NO}_x$  reduction [23]. Comparative studies showed that the partial oxidation of C1 reductants is different from that of C2–C4 reductants. It was found that formate was the main surface species during the partial oxidation of C1 reductants on  $\text{Ag}/\text{Al}_2\text{O}_3$ , and it had a low level of reactivity with nitrate

**Fig. 3** (a) In situ DRIFTS spectra of adsorbed species in the steady state on 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> in a flow of C<sub>2</sub>H<sub>5</sub>OH + NO + O<sub>2</sub> at various temperatures. species to form –NCO species [23]. The enolic species was the dominant surface species during partial oxidation of C<sub>2</sub>–C<sub>4</sub> reductants on Ag/Al<sub>2</sub>O<sub>3</sub>, and it had a high level of reactivity with nitrate species to form –NCO species.

On the basis of the studies described above, we summarize a reaction scheme for NO<sub>x</sub> reduction by different

reductants over Ag/Al<sub>2</sub>O<sub>3</sub>, as shown in Scheme 2. For C<sub>1</sub> reductants, both formate species and nitrates species adsorbed on Al site are the main intermediates, and they have a low level of reactivity with each other to form –NCO species adsorbed on Ag and Al sites, resulting in a low level of NO<sub>x</sub> reduction with C<sub>1</sub> reductants over

**Table 1** Bands observed on Ag/Al<sub>2</sub>O<sub>3</sub> catalysts during DRIFTS experiments and the corresponding surface species and vibrations to which they were assigned (s = symmetric, a = asymmetric,  $\nu$  = stretching,  $\delta$  = bending)

Wavenumber (cm <sup>-1</sup> )	Species	Vibration
1585–1589	Normal Al site bidentate nitrate NO <sub>3</sub> <sup>-</sup>	$\nu$ (N=O)
1300–1304	Isolated Al site bidentate nitrate NO <sub>3</sub> <sup>-</sup>	$\nu$ (N=O)
1633–1639	Enolic species RCH=CH-O <sup>-</sup>	$\nu_{as}$ (RCH=C-O <sup>-</sup> )
1412–1416	Enolic species RCH=CH-O <sup>-</sup>	$\nu_s$ (RCH=C-O <sup>-</sup> )
1336–1338	Enolic species RCH=CH-O <sup>-</sup>	$\delta$ (C-H)
1572–1579	Acetate CH <sub>3</sub> OO <sup>-</sup>	$\nu_{as}$ (COO <sup>-</sup> )
1464–1468	Acetate CH <sub>3</sub> OO <sup>-</sup>	$\nu_s$ (COO <sup>-</sup> )
1591–1595	Formate HCOO <sup>-</sup>	$\nu_{as}$ (COO <sup>-</sup> )
1390–1392	Formate HCOO <sup>-</sup>	$\delta$ (C-H)
1379	Formate HCOO <sup>-</sup>	$\nu_s$ (COO <sup>-</sup> )
2229–2239	Isocyanate -NCO	$\nu_{as}$ (NCO)

**Scheme 2** The proposed mechanisms of the SCR of NO<sub>x</sub> by different reductants over Ag/Al<sub>2</sub>O<sub>3</sub>

Ag/Al<sub>2</sub>O<sub>3</sub>. For C2, C3 and C4 reductants, the enolic species and the nitrates species adsorbed on Ag and Al sites are the key intermediates, and they have a high level of reactivity with each other to form -NCO species adsorbed on Ag and Al sites, resulting in a high level of NO<sub>x</sub> reduction with C2, C3 and C4 reductants over Ag/Al<sub>2</sub>O<sub>3</sub>. Therefore, C2, C3 and C4 reductants are likely to follow a similar reaction mechanism.

### 3 Poisoning of SO<sub>2</sub> on the SCR of NO<sub>x</sub> with Different Reductants Over Ag/Al<sub>2</sub>O<sub>3</sub>

#### 3.1 In Situ DRIFTS Study of Adsorbed Sulfate Species on Ag/Al<sub>2</sub>O<sub>3</sub>

Considering the practical usage of lean NO<sub>x</sub> catalysts, sulfur poisoning is one of the key difficulties that must be solved without reducing the NO<sub>x</sub> conversion ability of the catalyst [12–16, 33]. SO<sub>2</sub> is considered to be the most

important poison for a lean NO<sub>x</sub> catalyst because it can react further to form sulfate species, and the accumulation of the sulfate species on the catalyst can lead to a significant loss of catalyst performance. Thus, it is of interest to know how SO<sub>2</sub> influences Ag/Al<sub>2</sub>O<sub>3</sub> catalyst. There is still a limited understanding about the formation and configuration of the sulfate species over Ag/Al<sub>2</sub>O<sub>3</sub>. Here [34], the formation and structure of the sulfate species on Ag/Al<sub>2</sub>O<sub>3</sub> were studied in more detail by means of theoretical and experimental vibration spectra.

Figure 4 shows the in situ DRIFTS spectra of Ag/Al<sub>2</sub>O<sub>3</sub> at various temperatures in a flow of SO<sub>2</sub> + O<sub>2</sub> for a total of 210 min. Two weak bands appeared, at 1,346 cm<sup>-1</sup> and 1,313 cm<sup>-1</sup>, after exposing the catalyst to SO<sub>2</sub> + O<sub>2</sub> for 30 min at 473 K, and the band at 1,346 cm<sup>-1</sup> became predominant with increasing exposure time and temperature. According to the literature [32, 34], the bands at 1,346 cm<sup>-1</sup> and 1,178 cm<sup>-1</sup> were assigned to surface sulfate species linked to the Al sites, while the band at 1,313 cm<sup>-1</sup> was probably a similar surface sulfate species linked solely or partly to the Ag site. In addition, there was a distinct shift of the sulfate band from 1,346 cm<sup>-1</sup> to 1,364 cm<sup>-1</sup>, which may be caused by the accumulation of sulfate species by the reaction of SO<sub>2</sub> + O<sub>2</sub> with Ag/Al<sub>2</sub>O<sub>3</sub>. A similar experiment was carried out on the surface of pure  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> (result not shown). In comparison with the spectra of Ag/Al<sub>2</sub>O<sub>3</sub> (Fig. 4), the bands at 1,346 cm<sup>-1</sup> and 1,178 cm<sup>-1</sup> were also observed in the spectra of  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>, indicating that the sulfate species formed mostly on  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> [35, 36]. Furthermore, the band at 1,346 cm<sup>-1</sup> shifting to 1,369 cm<sup>-1</sup> arising from the accumulation of surface sulfate species was also in good agreement with what has been found in Fig. 4. In addition, the

**Fig. 4** In situ DRIFTS spectra of adsorbed sulfate species on 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> in a flow of SO<sub>2</sub> + O<sub>2</sub> at various temperatures. Conditions: SO<sub>2</sub>, 80 ppm; O<sub>2</sub>, 10%

disappearance of 1,313 cm<sup>-1</sup> peak on pure  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> further suggests that this band observed on Ag/Al<sub>2</sub>O<sub>3</sub> is related with sulfate species on the Ag site.

To gain insights into the nature of the species formed on the SO<sub>2</sub>-poisoned Ag/Al<sub>2</sub>O<sub>3</sub>, we examined temperature programmed desorption (TPD) curve for Ag/Al<sub>2</sub>O<sub>3</sub> after exposure to 80 ppm SO<sub>2</sub> in 10% O<sub>2</sub> at 673 K for 10 h, by monitoring SO<sub>2</sub> (*m/e* = 64) and O<sub>2</sub> (*m/e* = 32) signals. For comparison, TPD pattern of  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> poisoned by 80 ppm SO<sub>2</sub> was recorded under the same conditions. As shown in Fig. 5, SO<sub>2</sub> desorbed in two peaks for SO<sub>2</sub>-poisoned Ag/Al<sub>2</sub>O<sub>3</sub>, centered at 889 K and 1,206 K, respectively (top a line). In contrast with SO<sub>2</sub>-poisoned Ag/Al<sub>2</sub>O<sub>3</sub>, the TPD spectrum of SO<sub>2</sub>-poisoned  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> showed only a peak centered about 1,205 K (bottom b line). These desorption peaks at 889 K and 1,206 K are associated with decomposition of two different kinds of surface sulfate species on Ag/Al<sub>2</sub>O<sub>3</sub>. According to the literature, Al<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub> was formed through treatment of alumina with SO<sub>2</sub>, and it decomposed to yield alumina oxide at 1,073–1,193 K [37]. Compared Fig. 5a and b, the high-temperature peak centered around 1,206 K should be derived from the thermally stable sulfate species formed on the Al site, and its IR bands have been observed at 1,346 cm<sup>-1</sup> and 1,178 cm<sup>-1</sup> in Fig. 4. The low-temperature peak centered around 889 K should be attributed to SO<sub>2</sub> decomposed from the sulfate species formed on the Ag site, and its IR band has also been observed at 1,313 cm<sup>-1</sup> in Fig. 4. Therefore, the TPD results also provide clear evidences for the formation of sulfate species on Ag and Al sites by the reaction of Ag/Al<sub>2</sub>O<sub>3</sub> with SO<sub>2</sub>.

**Fig. 5** TPD spectra of SO<sub>2</sub> of 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> and  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> poisoned by 80 ppm SO<sub>2</sub> for 10 h at 673 K: (a) SO<sub>2</sub>-poisoned Ag/Al<sub>2</sub>O<sub>3</sub> and (b) SO<sub>2</sub>-poisoned  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>

### 3.2 Conformational Analysis of Adsorbed Sulfate Species on Al<sub>2</sub>O<sub>3</sub> by DFT Calculations

As mentioned above, sulfate species were formed mostly on the  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> support. Accordingly, we designed bidentate and tridentate models of sulfate species for calculation to obtain a better analysis of the nature of the sulfate species on Al<sub>2</sub>O<sub>3</sub>, and to explain the phenomenon of the blue shift for the in situ DRIFTS spectra.

The chemical structures of the models calculated for bidentate sulfate species on Al<sub>2</sub>O<sub>3</sub> are shown in Fig. 6. Model a was adopted to simulate the lower coverage state, and model b was adopted for the simulation of the higher coverage state. The optimized structures and the simulated

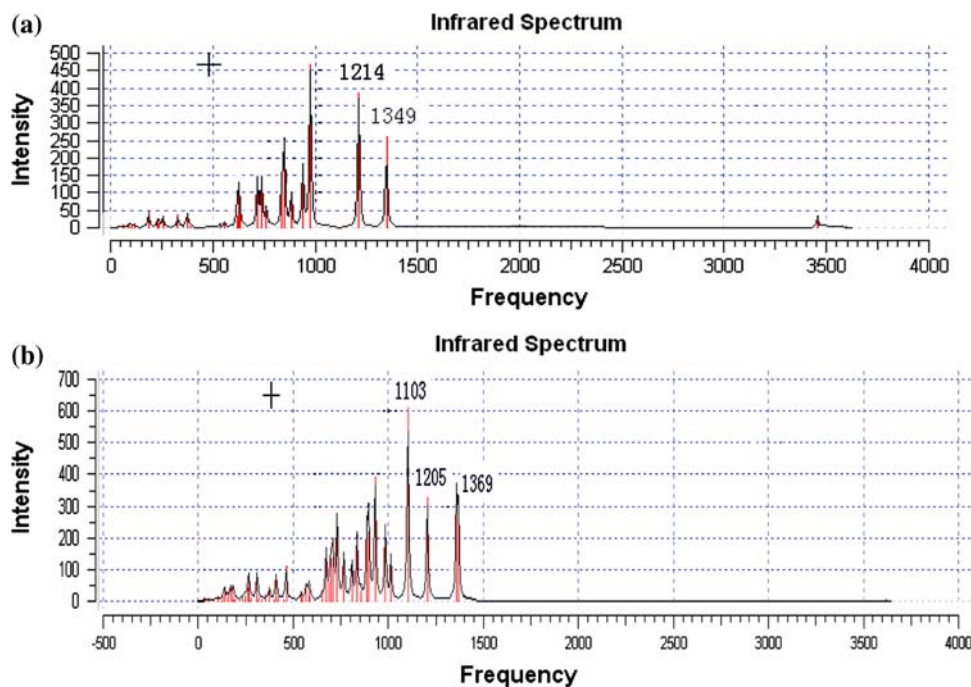

**Fig. 6** Models calculated for the bidentate sulfate species formed on Al<sub>2</sub>O<sub>3</sub>

**Fig. 7** Optimized configuration of the models calculated for the bidentate sulfate species formed on Al<sub>2</sub>O<sub>3</sub>

**Fig. 8** Calculated vibrational IR spectra for the bidentate sulfate species formed on  $\text{Al}_2\text{O}_3$

spectra for bidentate sulfate species are presented in Fig. 7 and 8, respectively. As can be seen from Fig. 8a, the  $\nu_{\text{as}}(\text{OSO})$  vibration frequency of model a was calculated as  $1,349 \text{ cm}^{-1}$  with  $260 \text{ km/mol}$  intensity, which was close to the experimental value of  $1,346 \text{ cm}^{-1}$  with strong adsorption, and the  $\nu_{\text{s}}(\text{OSO})$  vibration frequency of model a was calculated as  $1,214 \text{ cm}^{-1}$  with  $386 \text{ km/mol}$  intensity, which was  $36 \text{ cm}^{-1}$  higher than the experimental value of  $1,178 \text{ cm}^{-1}$  (Fig. 4). As shown in Fig. 8b, the  $\nu_{\text{as}}(\text{OSO})$  vibration frequency of model b was calculated as  $1,369 \text{ cm}^{-1}$  with  $273 \text{ km/mol}$  intensity, which was very close to the experimental value of  $1,364 \text{ cm}^{-1}$ , and the  $\nu_{\text{s}}(\text{OSO})$  vibration frequency of model b was calculated as  $1,205 \text{ cm}^{-1}$  with  $327 \text{ km/mol}$  intensity, which was  $27 \text{ cm}^{-1}$  higher than the experimental value of  $1,178 \text{ cm}^{-1}$  (Fig. 4). When comparing the frequency of the calculated model a with b for bidentate sulfate species, we observe a significant phenomenon; namely, the band shifted from  $1,349 \text{ cm}^{-1}$  to  $1,369 \text{ cm}^{-1}$  arising from the accumulation of surface sulfate species, which was in good agreement with the experimental shift of  $1,346\text{--}1,364 \text{ cm}^{-1}$ .

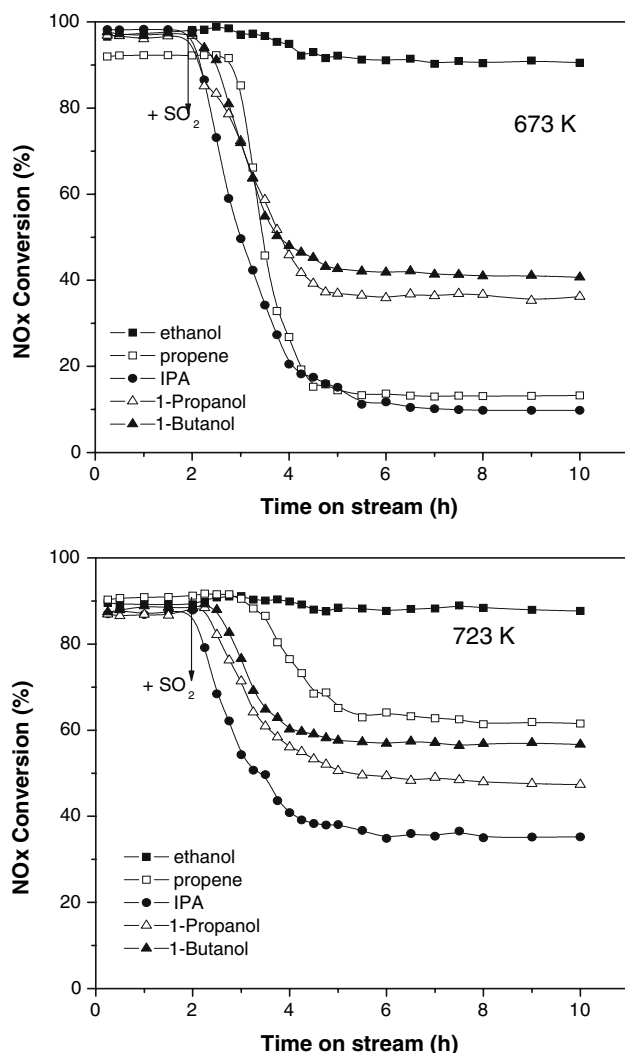

The models of tridentate sulfate species at lower and higher coverage state were calculated in an earlier study [34]. Considering that the calculated results could not be coincident with the real DRIFTS data, the results are not discussed in detail here. Accordingly, from a comparison of theoretical and experimental vibration spectra, it was found that the models of bidentate sulfate species are suitable for investigating the configuration of the sulfate species on  $\text{Al}_2\text{O}_3$ . Moreover, at the lower coverage state, bidentate and tridentate sulfate species might coexist on the

surface of the catalyst. The accumulation of sulfate species on the surface could well account for the blue shift of the sulfate species in the IR spectra [34].

### 3.3 Reaction of $\text{Ag}/\text{Al}_2\text{O}_3$ -Reductant System for the SCR of $\text{NO}_x$ in the Presence of $\text{SO}_2$

Earlier, we explained the different influences of  $\text{SO}_2$  on the  $\text{NO}_x$  reduction by  $\text{C}_2\text{H}_5\text{OH}$ ,  $\text{C}_3\text{H}_6$  and IPA [16, 32, 38]. Here, the highly efficient systems of  $\text{Ag}/\text{Al}_2\text{O}_3$ -C2 reductant ( $\text{C}_2\text{H}_5\text{OH}$ ), C3 reductants ( $\text{C}_3\text{H}_6$ , IPA, 1-propanol) and C4 reductant (1-butanol) were selected to further study their  $\text{SO}_2$  tolerance for practical use.

The effect of  $\text{SO}_2$  addition to the feed gas mixture on the SCR activity over  $\text{Ag}/\text{Al}_2\text{O}_3$  was monitored as a function of time on-stream at  $673 \text{ K}$  and  $723 \text{ K}$ , which correspond to the temperatures for high  $\text{NO}_x$  conversions with C2, C3 and C4 reductants. As shown in Fig. 9, in the absence of  $\text{SO}_2$ , steady-state  $\text{NO}_x$  conversions of  $>90\%$  at  $673 \text{ K}$  were achieved with all of the reaction systems. However, the addition of  $80 \text{ ppm SO}_2$  to the feed gas had a different effect on each case. For C3 reductants,  $\text{NO}_x$  conversion was decreased dramatically compared with C2 and C4 reductants, suggesting that the presence of  $\text{SO}_2$  largely deactivates the SCR activity of  $\text{Ag}/\text{Al}_2\text{O}_3$  using C3 reductants. In the case of the C2 reductant, the  $\text{NO}_x$  conversion was increased slightly at short times, and then passed a maximum to reach a stable level. The final level of  $\text{NO}_x$  conversion seemed to be influenced slightly by  $\text{SO}_2$ , indicating that the catalytic system of  $\text{Ag}/\text{Al}_2\text{O}_3$ -C2

**Fig. 9** Effects of SO<sub>2</sub> addition to the feed gas mixture on the SCR activity with different reductants over 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> were monitored as a function of time on-stream at 673 K and at 723 K. Conditions: NO, 800 ppm; ethanol, 1,565 ppm; or propene, 1,714 ppm; or IPA, 1,043 ppm; or 1-propanol, 1,043 ppm; or 1-butanol, 783 ppm; O<sub>2</sub>, 10%; H<sub>2</sub>O, 10% in N<sub>2</sub> balance at a total flow rate of 2,000 cm<sup>3</sup>/min, GHSV = 50,000 h<sup>-1</sup>

reductant has the best SO<sub>2</sub> tolerance. By comparison, we can conclude that the Ag/Al<sub>2</sub>O<sub>3</sub>-C4 reductant catalytic system has the next best SO<sub>2</sub> tolerance. It should be noted that a similar decrease in SCR activity occurred upon addition of 80 ppm SO<sub>2</sub> to the feed gas at 723 K. However, the suppressive effect of SO<sub>2</sub> was smaller than that at 673 K. Thus, we conclude that the reaction temperature is very important in NO<sub>x</sub> reduction in the presence of SO<sub>2</sub>. In general, the lower the reaction temperature, the greater the negative effect of SO<sub>2</sub>.

The results of the activity tests described above showed that the presence of SO<sub>2</sub> in the feed gas can markedly depress the catalytic activity of NO<sub>x</sub> reduction for C3 and C4 reductants. In contrast, no pronounced deactivation

effect of SO<sub>2</sub> was observed for the C2 reductant under identical experimental conditions. The efficiency order of the reductants for the SCR of NO<sub>x</sub> over Ag/Al<sub>2</sub>O<sub>3</sub> in the presence of SO<sub>2</sub> is proposed as follows: C2 > C4 > C3. The difference indicates that, in the presence of SO<sub>2</sub>, the reaction mechanism of the SCR of NO<sub>x</sub> by C2 reductant over Ag/Al<sub>2</sub>O<sub>3</sub> is different from that using C3 or C4 reductants.

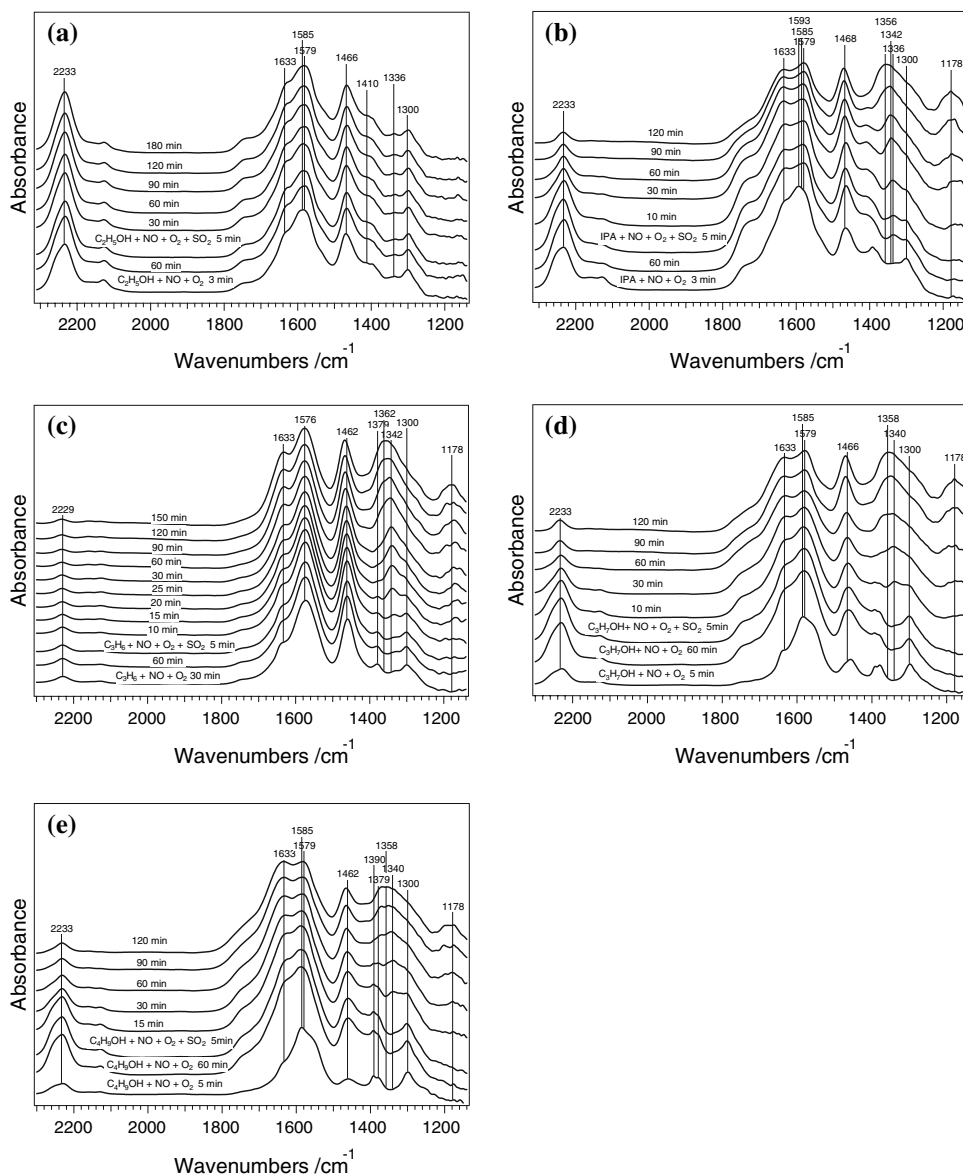

### 3.4 SO<sub>2</sub> Poisoning Mechanism in the SCR of NO<sub>x</sub> Over Ag/Al<sub>2</sub>O<sub>3</sub> by Different Reductants

As mentioned above, the presence of SO<sub>2</sub> can markedly depress the catalytic activity of NO<sub>x</sub> reduction for C3 and C4 reductants, while SO<sub>2</sub> hardly affects the catalytic activity of NO<sub>x</sub> reduction for the C2 reductant under identical experimental conditions. To gain more information about the sulfur-tolerant catalytic systems, it is crucial to put the emphasis on investigating different mechanisms for each case, as discussed below.

To better investigate the effect of SO<sub>2</sub> on Ag/Al<sub>2</sub>O<sub>3</sub> in the flow of different NO<sub>x</sub> + O<sub>2</sub> + reductant, we performed the in situ DRIFTS experiments as follows: when the reaction reached a steady state (at 60 min), 80 ppm SO<sub>2</sub> was introduced into the feed gas at 673 K. Figure 10a–e show the influence of SO<sub>2</sub> on various catalytic systems at 673 K. The first two spectra in Fig. 10a–e were taken under SO<sub>2</sub>-free flow and other spectra were taken in the presence of 80 ppm SO<sub>2</sub> at different time. We can observe that NO<sub>x</sub> reduction is influenced strongly by different reductants in the presence of SO<sub>2</sub>. When using C<sub>2</sub>H<sub>5</sub>OH as a reductant (Fig. 10a), no obvious difference was observed among all the spectra by introducing SO<sub>2</sub> into the feed gas. Since there was no sulfate species formed on Ag/Al<sub>2</sub>O<sub>3</sub>, we can conclude that SO<sub>2</sub> hardly affects the NO<sub>x</sub> reduction by C<sub>2</sub>H<sub>5</sub>OH over Ag/Al<sub>2</sub>O<sub>3</sub>. This might explain the high efficiency of NO<sub>x</sub> reduction with C<sub>2</sub>H<sub>5</sub>OH over Ag/Al<sub>2</sub>O<sub>3</sub> in the presence of SO<sub>2</sub>. In the case with IPA as a reductant (Fig. 10b), a new sulfate species peak appeared at 1,342 cm<sup>-1</sup>, and its intensity increased gradually and shifted to 1,356 cm<sup>-1</sup>, along with another increasing peak at 1,178 cm<sup>-1</sup>. At the same time, both the nitrates peak (1,300 cm<sup>-1</sup>) and the -NCO species peak (2,233 cm<sup>-1</sup>) decreased in intensity with increased exposure time. The results confirmed that the formation of sulfates species on Ag/Al<sub>2</sub>O<sub>3</sub> inhibited the formation of NO<sub>3</sub><sup>-</sup>, and suppressed the reaction of enolic species with NO<sub>3</sub><sup>-</sup> to form -NCO species, which is responsible for the poor reduction of NO<sub>x</sub> with IPA over Ag/Al<sub>2</sub>O<sub>3</sub> in the presence of SO<sub>2</sub>.

Very similar IR results were obtained for other C3 and C4 reductants, as shown in Fig. 10c–e. In all cases, the formation of surface sulfate species and its negative effect

**Fig. 10** (a) Changes of in situ DRIFTS spectra of adsorbed species on 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> at 673 K in a flow of C<sub>2</sub>H<sub>5</sub>OH + NO + O<sub>2</sub> + SO<sub>2</sub>. Before the measurement, the catalyst was exposed to a flow of C<sub>2</sub>H<sub>5</sub>OH + NO + O<sub>2</sub> for 60 min at 673 K. Conditions: NO, 800 ppm; C<sub>2</sub>H<sub>5</sub>OH, 1,565 ppm; SO<sub>2</sub>, 80 ppm; O<sub>2</sub>, 10%. (b) Changes of in situ DRIFTS spectra of adsorbed species on 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> at 673 K in a flow of IPA + NO + O<sub>2</sub> + SO<sub>2</sub>. Before the measurement, the catalyst was exposed to a flow of IPA + NO + O<sub>2</sub> for 60 min at 673 K. Conditions: NO, 800 ppm; IPA, 1,043 ppm; SO<sub>2</sub>, 80 ppm; O<sub>2</sub>, 10%. (c) Changes of in situ DRIFTS spectra of adsorbed species on 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> at 673 K in a flow of C<sub>3</sub>H<sub>6</sub> + NO + O<sub>2</sub> + SO<sub>2</sub>. Before the measurement, the catalyst was exposed to a flow of

C<sub>3</sub>H<sub>6</sub> + NO + O<sub>2</sub> for 60 min at 673 K. Conditions: NO, 800 ppm; C<sub>3</sub>H<sub>6</sub>, 1,714 ppm; SO<sub>2</sub>, 80 ppm; O<sub>2</sub>, 10%. (d) Changes of in situ DRIFTS spectra of adsorbed species on 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> at 673 K in a flow of C<sub>3</sub>H<sub>7</sub>OH + NO + O<sub>2</sub> + SO<sub>2</sub>. Before the measurement, the catalyst was exposed to a flow of C<sub>3</sub>H<sub>7</sub>OH + NO + O<sub>2</sub> for 60 min at 673 K. Conditions: NO, 800 ppm; C<sub>3</sub>H<sub>7</sub>OH, 1,043 ppm; SO<sub>2</sub>, 80 ppm; O<sub>2</sub>, 10%. (e) Changes of in situ DRIFTS spectra of adsorbed species on 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> at 673 K in a flow of C<sub>4</sub>H<sub>9</sub>OH + NO + O<sub>2</sub> + SO<sub>2</sub>. Before the measurement, the catalyst was exposed to a flow of C<sub>4</sub>H<sub>9</sub>OH + NO + O<sub>2</sub> for 60 min at 673 K. Conditions: NO, 800 ppm; C<sub>4</sub>H<sub>9</sub>OH, 783 ppm; SO<sub>2</sub>, 80 ppm; O<sub>2</sub>, 10%

on the formation of NO<sub>3</sub><sup>-</sup> and -NCO species were observed. The results suggested that the SCR activity of NO<sub>x</sub> reduction by various C3 or C4 reductants was markedly suppressed by the presence of SO<sub>2</sub>. The results were in good agreement with the activity results.

It is worth noting that C2, C3 and C4 alcohols as reductants followed similar mechanisms during the SCR of NO<sub>x</sub>. However, in the presence of SO<sub>2</sub>, the C2 reductant had the best SO<sub>2</sub> tolerance. This was due to the different enolic species formed from the partial oxidation of

different alcohols on Ag/Al<sub>2</sub>O<sub>3</sub>. We assume that the enolic species formed from the partial oxidation of the C2 reductant contain mainly two carbon atoms [7, 9]. The presence of C2 enolic species could inhibit the formation of sulfate species, therefore the reaction between C2 enolic species and nitrates to form –NCO species on Ag/Al<sub>2</sub>O<sub>3</sub> was not influenced by the presence of SO<sub>2</sub>. However, the enolic species derived from the partial oxidation of C3 reductants could contain three carbon atoms. The presence of C3 enolic species could not inhibit the formation of sulfate. Therefore, the surface sulfate species inhibited the formation of surface nitrates, which subsequently inhibited the reaction between C3 enolic species and nitrates to form –NCO species on Ag/Al<sub>2</sub>O<sub>3</sub>. The enolic species originated from the partial oxidation of a C4 reductant mostly contain four carbon atoms, together with a small amount of enolic species containing three or two carbon atoms. Therefore, the catalytic system with a C2 reductant has the best SO<sub>2</sub> tolerance, and that with C4 reductant has the next best SO<sub>2</sub> tolerance, followed by C3 reductants. It is possible that the C2 enolic species has higher reactivity with surface sulfate to reduce it into SO<sub>2</sub> than C3 and C4 enolic species.

The relationship between a catalyst–reductant system and SO<sub>2</sub> tolerance can be described as:

In general, catalyst composition has been tuned to improve its SO<sub>2</sub> tolerance, with success in many cases, such as V<sub>2</sub>O<sub>5</sub>/TiO<sub>2</sub>. Here, we present a novel idea that it is possible to alter the surface reaction to synthesize a SO<sub>2</sub>-resistant surface structure in situ by using different reactants.

#### 4 Effect and the Promotion Mechanism of H<sub>2</sub> on the SCR of NO<sub>x</sub> with Different Reductants Over Ag/Al<sub>2</sub>O<sub>3</sub>

##### 4.1 Effect of H<sub>2</sub> on Catalytic Activity

As discussed above, the Ag/Al<sub>2</sub>O<sub>3</sub> catalyst has a very high activity for NO<sub>x</sub> reduction by C2, C3 and C4 alcohols. Nevertheless, this catalyst shows a low activity at temperatures below ~600 K for the SCR of NO<sub>x</sub> by lower hydrocarbons, and this is a major disadvantage of this technology. H<sub>2</sub> in combination with hydrocarbons has been reported to boost the low-temperature activity of Ag catalysts significantly [20, 21, 39–42]. However, the interpretation of these results is open to debate. On the basis of the previous studies, we have investigated in detail the effect of H<sub>2</sub> on the surface intermediates during the SCR of NO<sub>x</sub> by C<sub>3</sub>H<sub>6</sub> [43]. Moreover, we were the first to

**Fig. 11** NO<sub>x</sub> conversion (a, b) for the SCR of NO<sub>x</sub> by C<sub>3</sub>H<sub>6</sub> over 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> catalyst in the absence of 1% H<sub>2</sub> (a) and in the presence of H<sub>2</sub> (b). Conditions: NO, 800 ppm; C<sub>3</sub>H<sub>6</sub>, 1,714 ppm; O<sub>2</sub>, 10% in N<sub>2</sub> balance at total flow rate 2,000 cm<sup>3</sup>/min, GHSV = 50,000 h<sup>-1</sup>

report the promotional effect of H<sub>2</sub> on the SCR of NO<sub>x</sub> by C<sub>2</sub>H<sub>5</sub>OH [22].

Figures 11 and 12 showed the NO<sub>x</sub> conversions for NO<sub>x</sub>/O<sub>2</sub>/C<sub>3</sub>H<sub>6</sub> and NO<sub>x</sub>/O<sub>2</sub>/C<sub>2</sub>H<sub>5</sub>OH reactions with or without 1% H<sub>2</sub> over Ag/Al<sub>2</sub>O<sub>3</sub> catalyst as a function of temperature. As shown in Fig. 11, the NO<sub>x</sub> conversion for the SCR of NO<sub>x</sub> by C<sub>3</sub>H<sub>6</sub> in the absence of H<sub>2</sub> was less than 10% within the temperature range of 423–573 K, and the maximum NO<sub>x</sub> conversion of 97% was achieved at 723 K. Clearly, the addition of H<sub>2</sub> enhanced NO<sub>x</sub> conversion significantly, especially in the temperature range of 473–623 K. As for the case using C<sub>2</sub>H<sub>5</sub>OH as a reductant, the reduction of NO<sub>x</sub> was also enhanced significantly by the addition of H<sub>2</sub> even if in the presence of H<sub>2</sub>O, especially in the temperature range of 423–523 K, as shown in Fig. 12. Compared with the cases without H<sub>2</sub>, the NO<sub>x</sub> conversion with H<sub>2</sub> was not significantly different from that without H<sub>2</sub> at temperatures higher than 623 K. This is not due to thermodynamic limitation, but due to the selectivity of reductant. At high temperatures, the reaction between the reductant and oxygen resulted in a shortage of C<sub>3</sub>H<sub>6</sub> and C<sub>2</sub>H<sub>5</sub>OH reductants, and H<sub>2</sub> was also consumed totally by oxygen. Therefore, the presence of H<sub>2</sub> could not improve the high-temperature reaction activity.

##### 4.2 GC-MS Analysis of the Effect of H<sub>2</sub> on the Gaseous Products in the SCR of NO<sub>x</sub> Over Ag/Al<sub>2</sub>O<sub>3</sub>

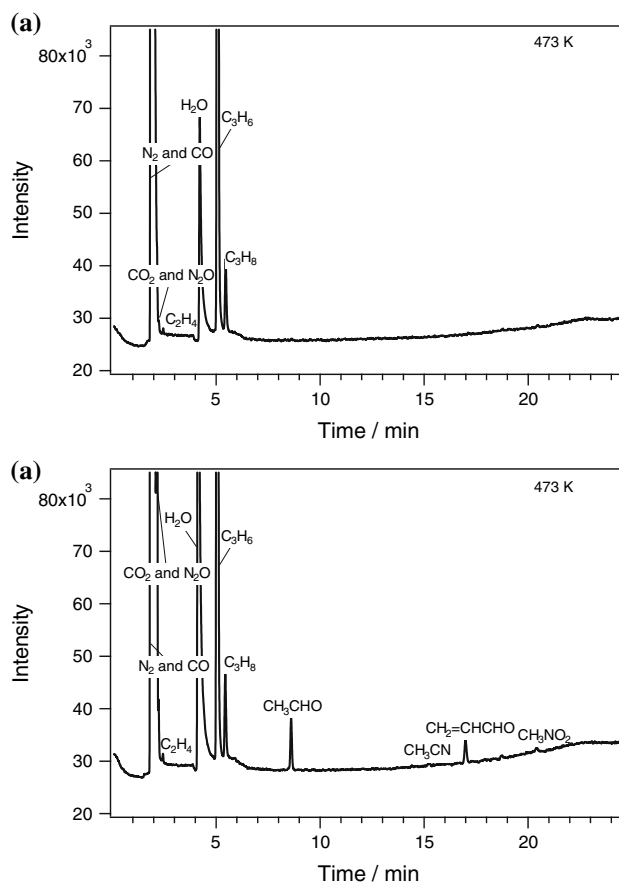

The main gaseous products in the SCR of NO<sub>x</sub> by hydrocarbons and oxygenated hydrocarbons over Ag/Al<sub>2</sub>O<sub>3</sub>

**Fig. 12** NO<sub>x</sub> conversion (a, b) for the SCR of NO<sub>x</sub> by C<sub>2</sub>H<sub>5</sub>OH over 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> catalyst in the absence of H<sub>2</sub> (a) and in the presence of 1% H<sub>2</sub> (b). Conditions: NO, 800 ppm; C<sub>2</sub>H<sub>5</sub>OH, 1,565 ppm; O<sub>2</sub>, 10%; H<sub>2</sub>O, 10% in N<sub>2</sub> balance at a total flow rate of 2,000 cm<sup>3</sup>/min, GHSV = 50,000 h<sup>-1</sup>

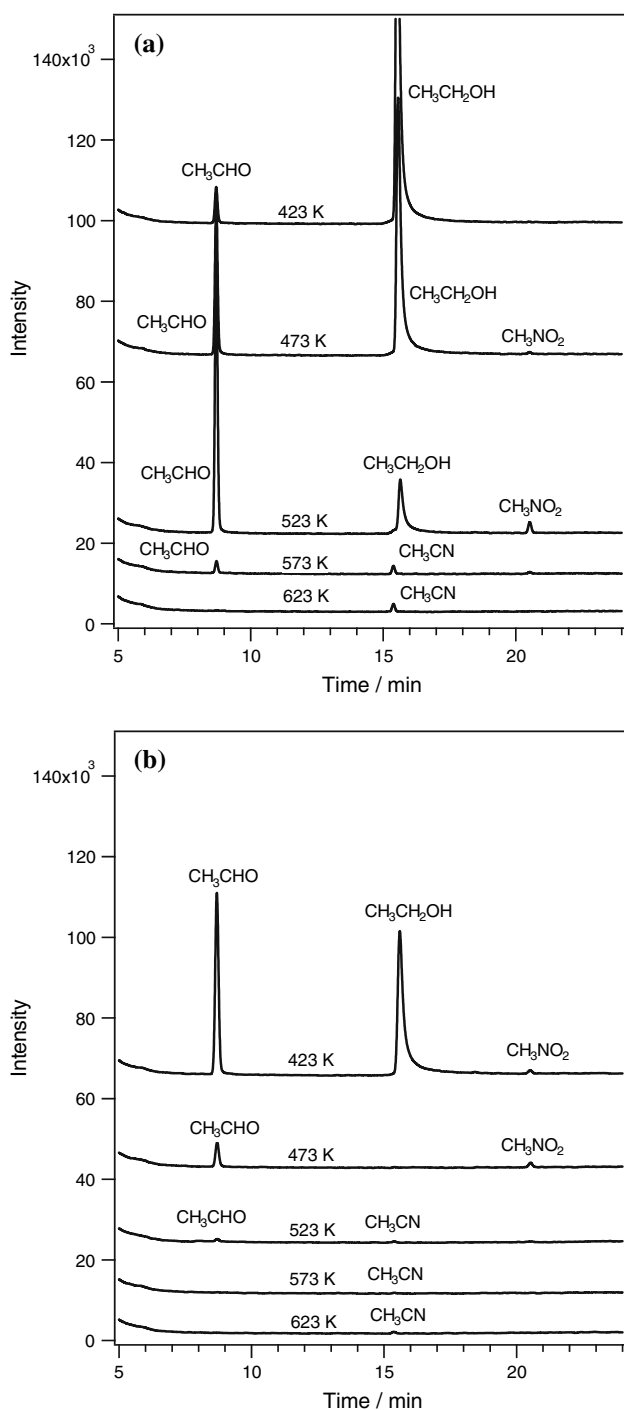

catalyst were N<sub>2</sub>, CO<sub>2</sub> and H<sub>2</sub>O, accompanied by trace oxygen-containing and nitrogen-containing compounds [3, 10, 17]. Previous studies pointed out that the oxygen-containing and nitrogen-containing compounds could be the intermediates related with the reaction pathway of NO<sub>x</sub> reduction [44, 45]. Therefore, it is possible to deduce a reaction pathway by following the origin of trace products. GC-MS measurement was used to monitor these trace products. Figure 13 shows the GC-MS chromatograms of the gas phase products of the SCR of NO<sub>x</sub> by C<sub>3</sub>H<sub>6</sub> over Ag/Al<sub>2</sub>O<sub>3</sub> in the absence or in the presence of H<sub>2</sub> at 473 K in the steady state, respectively. In the absence of H<sub>2</sub>, despite small amounts of H<sub>2</sub>O and CO<sub>2</sub> detected along with unreacted C<sub>3</sub>H<sub>6</sub> and C<sub>3</sub>H<sub>8</sub> (impurity), there was no other oxygen-containing and nitrogen-containing compounds observed at 473 K (Fig. 13a). Unlike the case without H<sub>2</sub>, the presence of H<sub>2</sub> resulted in the appearance of partial oxidation products of C<sub>3</sub>H<sub>6</sub> at same temperature (473 K), such as acetaldehyde and acrolein, accompanied by large amounts of H<sub>2</sub>O and CO<sub>2</sub> as final products (Fig. 13b). In addition, traces of CH<sub>3</sub>CN and CH<sub>3</sub>NO<sub>2</sub> were detected as nitrogen-containing products (Fig. 13b). At temperatures above 573 K, no significant difference in the variety of oxygen-containing and nitrogen-containing compounds was found during the NO<sub>x</sub> reduction by C<sub>3</sub>H<sub>6</sub> in the presence and in the absence of H<sub>2</sub> (data not shown). These results indicate that the addition of H<sub>2</sub> accelerates the NO<sub>x</sub> reduction reaction at low temperatures.

Figure 14a and b show the GC-MS chromatograms of the gas phase products of the SCR of NO<sub>x</sub> by C<sub>2</sub>H<sub>5</sub>OH over Ag/Al<sub>2</sub>O<sub>3</sub> in the absence or in the presence of H<sub>2</sub> at 473–623 K in the steady state. The light gaseous molecules,

**Fig. 13** (a) GC-MS chromatogram of gas products of C<sub>3</sub>H<sub>6</sub> + NO + O<sub>2</sub> reaction in the absence of H<sub>2</sub> at 473 K over 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> catalyst. Conditions: NO, 800 ppm; C<sub>3</sub>H<sub>6</sub>, 1,714 ppm; O<sub>2</sub>, 10% in N<sub>2</sub> balance at a total flow rate of 2,000 cm<sup>3</sup>/min, GHSV = 50,000 h<sup>-1</sup>. (b) GC-MS chromatogram of gas products of C<sub>3</sub>H<sub>6</sub> + NO + O<sub>2</sub> reaction in the presence of 1% H<sub>2</sub> at 473 K over 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> catalyst. Conditions: NO, 800 ppm; C<sub>3</sub>H<sub>6</sub>, 1,714 ppm; O<sub>2</sub>, 10% in N<sub>2</sub> balance at a total flow rate of 2,000 cm<sup>3</sup>/min, GHSV = 50,000 h<sup>-1</sup>

such as CO<sub>2</sub>, N<sub>2</sub>O, N<sub>2</sub>, and CO, were detected within 5 min retention time and the data were cut from the chromatograms. In the absence of H<sub>2</sub>, as shown in Fig. 14a, a small amount of CH<sub>3</sub>CHO was detected along with a large amount of unreacted C<sub>2</sub>H<sub>5</sub>OH, but no other nitrogen-containing compound was observed at 423 K. The intensity of the CH<sub>3</sub>CHO peak increased gradually from 423 K to 523 K, and then decreased with further increasing temperature. At 523 K, where ~30% NO<sub>x</sub> conversion was achieved (Fig. 12), the production of CH<sub>3</sub>CHO was maximized and CH<sub>3</sub>NO<sub>2</sub> appeared. At 573 K, CH<sub>3</sub>CN appeared, accompanied by a disappearance of CH<sub>3</sub>NO<sub>2</sub>. However, in the presence of H<sub>2</sub>, CH<sub>3</sub>CHO was produced in significant amounts reaching a maximum at 423 K, along with the appearance of CH<sub>3</sub>NO<sub>2</sub> (Fig. 14b). At 473 K, the disappearance of C<sub>2</sub>H<sub>5</sub>OH and the traces of CH<sub>3</sub>CHO and CH<sub>3</sub>NO<sub>2</sub> under these conditions suggested that the reaction proceeded efficiently.

**Fig. 14** (a) GC-MS chromatogram of gas products of C<sub>2</sub>H<sub>5</sub>OH + NO + O<sub>2</sub> reaction in the absence of H<sub>2</sub> at various temperatures over 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> catalyst. Conditions: NO, 800 ppm; C<sub>2</sub>H<sub>5</sub>OH, 1,565 ppm; O<sub>2</sub>, 10%; H<sub>2</sub>O, 10% in N<sub>2</sub> balance at a total flow rate of 2,000 cm<sup>3</sup>/min, GHSV = 50,000 h<sup>-1</sup>. (b) GC-MS chromatogram of gas products of C<sub>2</sub>H<sub>5</sub>OH + NO + O<sub>2</sub> reaction in the presence of 1% H<sub>2</sub> at various temperatures over 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> catalyst. Conditions: NO, 800 ppm; C<sub>2</sub>H<sub>5</sub>OH, 1,565 ppm; O<sub>2</sub>, 10%; H<sub>2</sub>O, 10% in N<sub>2</sub> balance at a total flow rate of 2,000 cm<sup>3</sup>/min, GHSV = 50,000 h<sup>-1</sup>

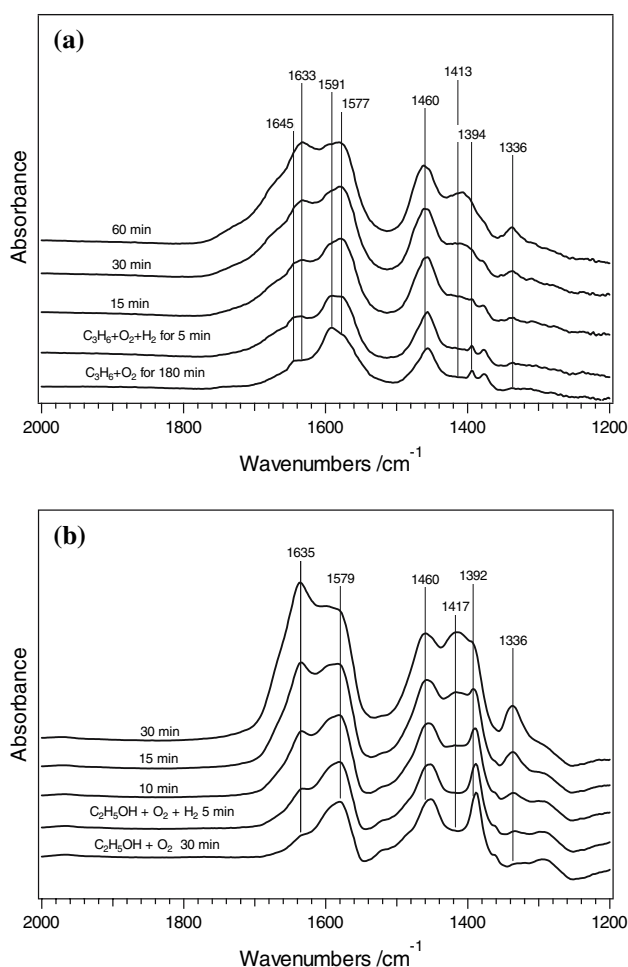

In comparison with the cases with H<sub>2</sub> (Figs. 13b and 14b) and without H<sub>2</sub> (Fig. 13a and 14a), it is obvious that the presence of H<sub>2</sub> promoted the formation of oxygen-containing molecules (such as CH<sub>3</sub>CHO) and nitrogen-containing molecules (such as CH<sub>3</sub>NO<sub>2</sub>) during the SCR of NO<sub>x</sub> by both C<sub>3</sub>H<sub>6</sub> and C<sub>2</sub>H<sub>5</sub>OH. On the basis of the analysis of gas products, it is noticeable that the addition of H<sub>2</sub> significantly promoted the partial oxidation of C<sub>3</sub>H<sub>6</sub> or C<sub>2</sub>H<sub>5</sub>OH to CH<sub>3</sub>CHO. As we proposed earlier, enolic surface species (RCH=CH-O<sup>-</sup>)-M was formed when CH<sub>3</sub>CHO was adsorbed on the surface of Ag/Al<sub>2</sub>O<sub>3</sub> [7, 9, 10]. The formation of enolic surface species could be attributed to the CH<sub>3</sub>CHO isomerization between the gaseous phase and the catalyst surface. It has been pointed out that the enolic species is related to the efficiency of NO<sub>x</sub> reduction by C<sub>2</sub>H<sub>5</sub>OH or C<sub>3</sub>H<sub>6</sub> over Ag/Al<sub>2</sub>O<sub>3</sub> [7, 9, 10]. We studied the partial oxidation of C<sub>3</sub>H<sub>6</sub> and C<sub>2</sub>H<sub>5</sub>OH on Ag/Al<sub>2</sub>O<sub>3</sub> in the presence of H<sub>2</sub> and its effect on the SCR of NO<sub>x</sub> using in situ DRIFTS method, respectively.

#### 4.3 H<sub>2</sub> Promotion Mechanism in the SCR of NO<sub>x</sub> by C<sub>2</sub>H<sub>5</sub>OH or C<sub>3</sub>H<sub>6</sub> Over Ag/Al<sub>2</sub>O<sub>3</sub>

The effect of hydrogen on the formation of surface oxygenated species on Ag/Al<sub>2</sub>O<sub>3</sub> was studied by in situ DRIFTS. Figure 15a shows the effect of H<sub>2</sub> on the partial oxidation of C<sub>3</sub>H<sub>6</sub> on Ag/Al<sub>2</sub>O<sub>3</sub> at 473 K. After exposing Ag/Al<sub>2</sub>O<sub>3</sub> to a flow of C<sub>3</sub>H<sub>6</sub> + O<sub>2</sub> for 180 min, the peak for C=C (1,645 cm<sup>-1</sup>), a weak peak for enolic species (1,633 cm<sup>-1</sup>), strong bands for acetate (1,577 cm<sup>-1</sup> and 1,460 cm<sup>-1</sup>) and the bands for formate (1591, 1394 cm<sup>-1</sup>) were observed [7, 9, 10, 23, 30–32]. The bands due to acetate were predominant at 473 K in the absence of H<sub>2</sub>. When H<sub>2</sub> was added to the flow of C<sub>3</sub>H<sub>6</sub> + O<sub>2</sub> at the same temperature, the bands due to adsorbed acetate (1,577 cm<sup>-1</sup> and 1,460 cm<sup>-1</sup>) were similarly observed on Ag/Al<sub>2</sub>O<sub>3</sub>. However, it should be noted that the peak at 1,633 cm<sup>-1</sup> for enolic species intensified gradually as a function of time, accompanied by the appearance of other peaks at 1,413 cm<sup>-1</sup> and 1,336 cm<sup>-1</sup> of the enolic species. After flowing H<sub>2</sub> for 60 min, the peak at 1,633 cm<sup>-1</sup> achieved maximum intensity. Accordingly, the enolic species and acetate became the predominant surface species in the presence of H<sub>2</sub>.

For using C<sub>2</sub>H<sub>5</sub>OH as a reductant, similar results were observed, as shown in Fig. 15b. After exposing Ag/Al<sub>2</sub>O<sub>3</sub> to a flow of C<sub>2</sub>H<sub>5</sub>OH + O<sub>2</sub> for 30 min at 423 K, the peaks of enolic species (1,635 cm<sup>-1</sup>), acetate (1,579 cm<sup>-1</sup> and 1,460 cm<sup>-1</sup>) and δ(C-H) of adsorbed acetate (1,392 cm<sup>-1</sup>)

**Fig. 15** (a) Dynamic changes of in situ DRIFTS spectra of 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> as a function of time in a flow of C<sub>3</sub>H<sub>6</sub> + O<sub>2</sub> + H<sub>2</sub> at 473 K. Before the measurement, the catalyst was exposed to a flow of C<sub>3</sub>H<sub>6</sub> + O<sub>2</sub> for 180 min at 473 K. Conditions: C<sub>3</sub>H<sub>6</sub>, 1,714 ppm; O<sub>2</sub>, 10%; H<sub>2</sub>, 1%. (b) Dynamic changes of in situ DRIFTS spectra of 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> as a function of time in a flow of C<sub>2</sub>H<sub>5</sub>OH + O<sub>2</sub> + H<sub>2</sub> at 423 K. Before the measurement, the catalyst was exposed to a flow of C<sub>2</sub>H<sub>5</sub>OH + O<sub>2</sub> for 30 min at 423 K. Conditions: C<sub>2</sub>H<sub>5</sub>OH, 1,565 ppm; O<sub>2</sub>, 10%; H<sub>2</sub>, 1%

were observed on Ag/Al<sub>2</sub>O<sub>3</sub> [7, 9, 10, 23, 30–32, 46]. When H<sub>2</sub> was added to the flow of C<sub>2</sub>H<sub>5</sub>OH + O<sub>2</sub> at 423 K, it should be noted that the band intensity of enolic species (1,635 cm<sup>-1</sup>, 1,417 cm<sup>-1</sup> and 1,336 cm<sup>-1</sup>) increased gradually as a function of time. After flowing H<sub>2</sub> for 30 min, the peak at 1,635 cm<sup>-1</sup> achieved maximum intensity, indicating that enolic species became the predominant surface species. On the basis of these observations, it is suggested that the presence of H<sub>2</sub> promotes the partial oxidation of C<sub>3</sub>H<sub>6</sub> and C<sub>2</sub>H<sub>5</sub>OH, especially the formation of enolic species at low temperature. In our previous study [43], we proposed that the molecular oxygen might be activated by the addition of H<sub>2</sub> over Ag/Al<sub>2</sub>O<sub>3</sub> catalyst, forming a peroxo-like species.

**Fig. 16** Dynamic changes of in situ DRIFTS spectra of 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> as a function of time in a flow of C<sub>3</sub>H<sub>6</sub> + NO + O<sub>2</sub> + H<sub>2</sub> at 523 K. Before the measurement, the catalyst was exposed to a flow of C<sub>3</sub>H<sub>6</sub> + NO + O<sub>2</sub> for 60 min at 523 K. Conditions: NO, 800 ppm; C<sub>3</sub>H<sub>6</sub>, 1,714 ppm; O<sub>2</sub>, 10%; H<sub>2</sub>, 1%

This species is highly active oxidant, and favorable to the partial oxidation of reductants.

To elucidate the effect of H<sub>2</sub> on the SCR of NO<sub>x</sub> by C<sub>3</sub>H<sub>6</sub>, we investigated dynamic changes of the reaction intermediates on the Ag/Al<sub>2</sub>O<sub>3</sub> by DRIFTS. Figure 16 shows the in situ DRIFTS spectra of Ag/Al<sub>2</sub>O<sub>3</sub> in a flow of C<sub>3</sub>H<sub>6</sub> + NO + O<sub>2</sub> and then C<sub>3</sub>H<sub>6</sub> + NO + O<sub>2</sub> + H<sub>2</sub>. After exposing the catalyst to a flow of C<sub>3</sub>H<sub>6</sub> + NO + O<sub>2</sub> for 60 min at 523 K, the enolic species (1,639 cm<sup>-1</sup>), nitrates (1,589 cm<sup>-1</sup> and 1,302 cm<sup>-1</sup>) and acetate (1,574 cm<sup>-1</sup> and 1,464 cm<sup>-1</sup>) were observed. By examining the intensity of each peak under a flow of C<sub>3</sub>H<sub>6</sub> + NO + O<sub>2</sub>, the nitrates (1,589 cm<sup>-1</sup> and 1,302 cm<sup>-1</sup>) appeared to dominate on Ag/Al<sub>2</sub>O<sub>3</sub> at this temperature. After adding H<sub>2</sub> to the mixture of C<sub>3</sub>H<sub>6</sub> + NO + O<sub>2</sub>, the bands of adsorbed nitrates (1,589 cm<sup>-1</sup> and 1,302 cm<sup>-1</sup>) and acetate (1,574 cm<sup>-1</sup> and 1,464 cm<sup>-1</sup>) were still visible on Ag/Al<sub>2</sub>O<sub>3</sub> at the same temperature, whereas the surface concentrations of the enolic species (1,639 cm<sup>-1</sup>) and -NCO species (2,233 cm<sup>-1</sup>) increased significantly with time. These results suggest strongly that the presence of H<sub>2</sub> enhances the formation of enolic species and -NCO species during the SCR of NO<sub>x</sub>. Considering the high reactivity of the enolic species with nitrates [7, 9, 10], it is reasonable that the formation of -NCO surface species is promoted in the presence of H<sub>2</sub>.

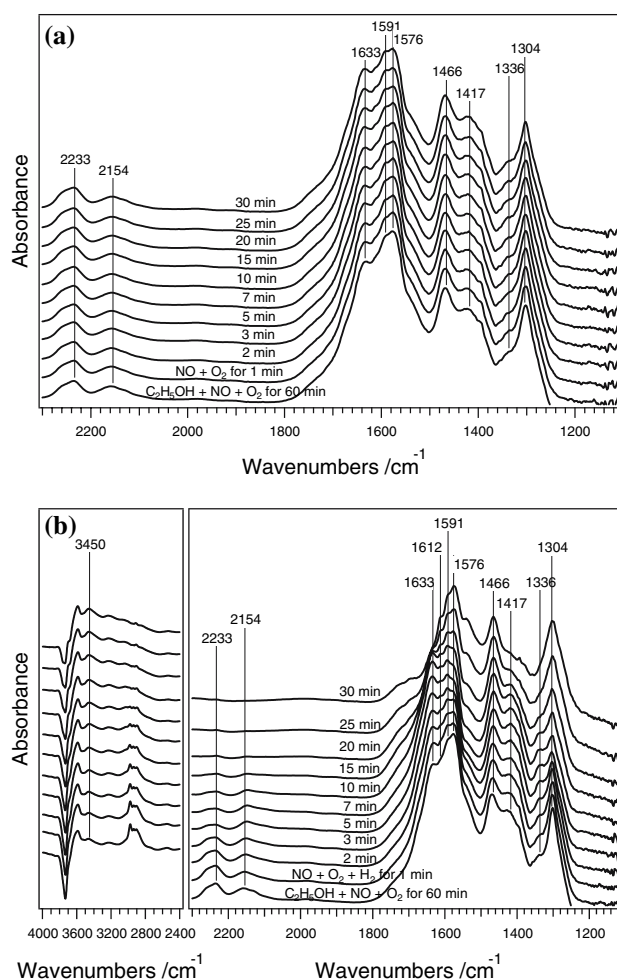

Similar in situ DRIFTS studies were performed in the SCR of NO<sub>x</sub> by C<sub>2</sub>H<sub>5</sub>OH. Figure 17 shows the in situ DRIFTS spectra of Ag/Al<sub>2</sub>O<sub>3</sub> in a flow of C<sub>2</sub>H<sub>5</sub>OH + NO + O<sub>2</sub> and then C<sub>2</sub>H<sub>5</sub>OH + NO + O<sub>2</sub> + H<sub>2</sub>. Compared with the case without H<sub>2</sub>, the significant change was that the surface concentration of the enolic species

**Fig. 17** Dynamic changes of in situ DRIFTS spectra of 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> as a function of time in a flow of C<sub>2</sub>H<sub>5</sub>OH + NO + O<sub>2</sub> + H<sub>2</sub> at 473 K. Before the measurement, the catalyst was exposed to a flow of C<sub>2</sub>H<sub>5</sub>OH + NO + O<sub>2</sub> for 60 min at 473 K. Conditions: NO, 800 ppm; C<sub>2</sub>H<sub>5</sub>OH, 1,565 ppm; O<sub>2</sub>, 10%; H<sub>2</sub>, 1%

(1,633 cm<sup>-1</sup>, 1,417 cm<sup>-1</sup> and 1,336 cm<sup>-1</sup>) increased significantly with time, and the peaks associated with this species became the most intense among all absorbed species peaks in 20 min. This result suggests strongly that the presence of H<sub>2</sub> facilitates the formation of enolic species during the NO<sub>x</sub> reduction by C<sub>2</sub>H<sub>5</sub>OH, even at very low temperature. Another obvious difference was that the bands for surface bidentate nitrates (1,591 cm<sup>-1</sup> and 1,304 cm<sup>-1</sup>) decreased with time, indicating low steady-state nitrates coverage in the presence of H<sub>2</sub>. Compared to the case with C<sub>3</sub>H<sub>6</sub> as a reductant in the presence of H<sub>2</sub> (Fig. 16), the peak at 2,235 cm<sup>-1</sup> assigned to -NCO decreased with time in the presence of H<sub>2</sub>. We postulated that -NCO could participate in the formation of other active species in the presence of H<sub>2</sub>, which was responsible for the enhancement of NO<sub>x</sub> conversion.

To obtain further information on the effect of H<sub>2</sub> on the whole reaction, the reactions of -NCO with NO + O<sub>2</sub>, with and without the addition of H<sub>2</sub>, were further investigated by in situ DRIFTS. After treating Ag/Al<sub>2</sub>O<sub>3</sub> in C<sub>2</sub>H<sub>5</sub>OH + NO + O<sub>2</sub> for 60 min at 523 K, as shown in Fig. 18a and b, a peak at 2,233 cm<sup>-1</sup> for -NCO and a peak at 2,154 cm<sup>-1</sup> for -CN were observed [17, 31]. As seen in Fig. 18a, when C<sub>2</sub>H<sub>5</sub>OH flow was interrupted, continual monitoring of the adsorbed species on Ag/Al<sub>2</sub>O<sub>3</sub> in the flow of NO + O<sub>2</sub> revealed that -NCO and -CN did not react with NO + O<sub>2</sub> in 30 min at 523 K. However, as shown in Fig. 18b, the intensity of the adsorbed -NCO bands decreased and disappeared in 20 min, indicating a strong reactivity of the adsorbed -NCO species in the flow of NO + O<sub>2</sub> + H<sub>2</sub> at this temperature. It is noticeable that a new peak at 1,612 cm<sup>-1</sup> in Fig. 18b appeared gradually,

**Fig. 18** (a) Dynamic changes of in situ DRIFTS spectra of 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> in a flow of NO + O<sub>2</sub> as a function of time at 523 K. Before the measurement, the catalyst was exposed to a flow of C<sub>2</sub>H<sub>5</sub>OH + NO + O<sub>2</sub> for 60 min at 523 K. Conditions: NO, 800 ppm; C<sub>2</sub>H<sub>5</sub>OH, 1,565 ppm; O<sub>2</sub>, 10%. (b) Dynamic changes of in situ DRIFTS spectra of 4 wt.% Ag/Al<sub>2</sub>O<sub>3</sub> in a flow of NO + O<sub>2</sub> + H<sub>2</sub> as a function of time at 523 K. Before the measurement, the catalyst was exposed to a flow of C<sub>2</sub>H<sub>5</sub>OH + NO + O<sub>2</sub> for 60 min at 523 K. Conditions: NO, 800 ppm; C<sub>2</sub>H<sub>5</sub>OH, 1,565 ppm; O<sub>2</sub>, 10%; H<sub>2</sub>, 1%

accompanied by the disappearance of -NCO, and this new peak may be due to a deformation mode of adsorbed NH<sub>x</sub> on Ag/Al<sub>2</sub>O<sub>3</sub> [47, 48]. At the same time, a weak peak was observed at 3,450 cm<sup>-1</sup>, which may be assigned to the stretching vibration mode of NH species [49]. On the basis of the results described above, the consumption of -NCO species may be related to the rapid hydrolysis of -NCO species in the flow of NO + O<sub>2</sub> + H<sub>2</sub>, resulting in the formation of NH<sub>x</sub> species.

On the basis of the results of the experiments and the mechanism proposed previously, we summarize a simplified reaction scheme for the reduction of NO<sub>x</sub> by C<sub>3</sub>H<sub>6</sub> and C<sub>2</sub>H<sub>5</sub>OH in the presence of H<sub>2</sub>. As shown in Scheme 3, the

**Scheme 3** The possible effect of H<sub>2</sub> on the SCR of NO<sub>x</sub> by C<sub>3</sub>H<sub>6</sub> and C<sub>2</sub>H<sub>5</sub>OH over Ag/Al<sub>2</sub>O<sub>3</sub>

presence of H<sub>2</sub> first promotes the partial oxidation of C<sub>3</sub>H<sub>6</sub> and C<sub>2</sub>H<sub>5</sub>OH to enolic species. Subsequently, in the case of C<sub>3</sub>H<sub>6</sub> as a reductant, the presence of H<sub>2</sub> accelerates the reaction between enolic species and nitrates to form key intermediates -NCO, and then enhances the reactions of enolic species and -NCO towards NO + O<sub>2</sub> to form N<sub>2</sub> as a final product. These lead to the corresponding enhancement of Ag/Al<sub>2</sub>O<sub>3</sub> in the SCR of NO<sub>x</sub> by C<sub>3</sub>H<sub>6</sub> in the presence of H<sub>2</sub>. As for C<sub>2</sub>H<sub>5</sub>OH as a reductant, besides the promotion effects mentioned above, the presence of H<sub>2</sub> further promotes the hydrolysis of -NCO to form NH<sub>x</sub> species, which was known to be highly active towards NO<sub>x</sub> reduction when using NH<sub>3</sub> as a reductant over Ag/Al<sub>2</sub>O<sub>3</sub> in the presence of H<sub>2</sub> [50]. Therefore, the formation of NH<sub>x</sub> species may be another reason that the addition of H<sub>2</sub> improves the reaction activity of NO<sub>x</sub> reduction by C<sub>2</sub>H<sub>5</sub>OH.

## 5 Application of Ag/Al<sub>2</sub>O<sub>3</sub>-C<sub>2</sub>H<sub>5</sub>OH-SCR System to a Heavy-duty Diesel Engine

### 5.1 Honeycomb Catalyst Engine Test

On the basis of the results obtained under laboratory conditions, we found that the Ag/Al<sub>2</sub>O<sub>3</sub> catalyst exhibits a high activity for the SCR of NO<sub>x</sub> with C<sub>2</sub>H<sub>5</sub>OH in the presence of H<sub>2</sub>O and SO<sub>2</sub>, and the best performance of Ag/Al<sub>2</sub>O<sub>3</sub> is achieved with 4% Ag loading [7]. Therefore, a bench test was carried out using the Ag/Al<sub>2</sub>O<sub>3</sub> washcoated honeycomb catalyst and C<sub>2</sub>H<sub>5</sub>OH as a reducing agent on a diesel engine under practical operating condition [19].

In order to investigate the influence of the exhaust gas temperature and GHSV of a honeycomb catalyst on NO<sub>x</sub> conversion, the impact of the exhaust components and THC (total hydrocarbons)/NO<sub>x</sub> ratio should be eliminated. Therefore, the engine was operated in the same mode at 3,450 rpm at full load in the following experiments. The THC/NO<sub>x</sub> ratio in effluent gas was fixed at 3.4 by C<sub>2</sub>H<sub>5</sub>OH injection. The temperature at the inlet of the catalyst was

adjusted by the heat exchanger, and GHSV was changed by the bypass valve.

Figure 19 shows the catalytic activity of the Ag/Al<sub>2</sub>O<sub>3</sub> honeycomb catalyst (SCR catalyst) with different GHSVs (30,000 h<sup>-1</sup>, 50,000 h<sup>-1</sup>, 80,000 h<sup>-1</sup>) at a fixed THC/NO<sub>x</sub> ratio of 3.4. As shown in Fig. 19a, the honeycomb catalyst showed a very high activity for the removal of NO<sub>x</sub> at the GHSV of 30,000 h<sup>-1</sup>. The maximal conversion of NO<sub>x</sub> was up to 93%, and the average conversion of NO<sub>x</sub> was ~77% in the wide temperature range of 543–743 K. Those results are similar to our results in the laboratory-scale test, which indicates that Ag/Al<sub>2</sub>O<sub>3</sub> has a realistic potential in reducing NO<sub>x</sub> under real diesel engine exhaust conditions. Increasing the GHSV from 30,000 h<sup>-1</sup> to 50,000 h<sup>-1</sup> and 80,000 h<sup>-1</sup>, the catalytic activity for the removal of NO<sub>x</sub> was decreased gradually. The curve of NO<sub>x</sub> conversion was shifted towards higher temperatures, and the average conversion of NO<sub>x</sub> was only ~52% in the wide temperature range of 593–763 K at a GHSV of 80,000 h<sup>-1</sup>. Figure 19b shows that THC conversions have no obvious change with the increase of GHSV. In addition, as shown in Fig. 19c, CO conversion was observed as negative value, indicating that CO was produced during the SCR of NO<sub>x</sub> by C<sub>2</sub>H<sub>5</sub>OH. It can be seen that the negative CO conversion decreased with the increase of GHSV from 30,000 h<sup>-1</sup> to 50,000 h<sup>-1</sup> and 80,000 h<sup>-1</sup>. Since CO production is in direct proportion to the NO<sub>x</sub> conversion, we propose that CO is not produced mainly from partial oxidation of HC, but from the C<sub>2</sub>H<sub>5</sub>OH-SCR of NO<sub>x</sub> process.

### 5.2 EURO III ESC Test of Honeycomb Catalysts

In order to make the original Sofim 8140-43 C EURO II diesel engine meet EURO III standards, the catalytic system for the removal of NO<sub>x</sub> was tested and optimized at the 13-mode test cycle for heavy-duty diesel engines.

Table 2 shows the EURO III ESC test results with different catalysts. It should be noted that the C<sub>2</sub>H<sub>5</sub>OH was not injected at idle speed. It can be seen that the NO<sub>x</sub> emission is much lower than that of the original engine over the SCR catalyst, which meets the EURO III regulation. However, the amount of the by-products such as CO, unburned THC increased and exceeded the EURO III limits. The increase of CO and unburned THC was due to the addition of ethanol as the reducing agent during the bench test on the HC-SCR-fitted engine. As a result, certain measures should be taken to reduce HC and CO simultaneously, such as using an oxidation catalyst with a low light-off temperature, or optimizing the strategy of the C<sub>2</sub>H<sub>5</sub>OH addition.

According to our previous research results [10], a Cu/Al<sub>2</sub>O<sub>3</sub> honeycomb oxidation catalyst was added directly

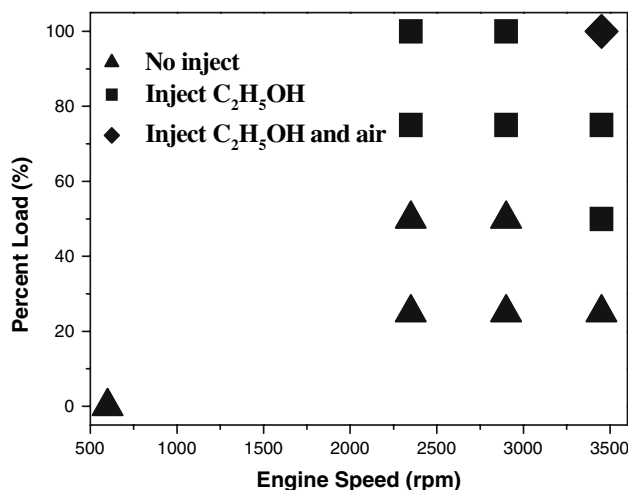

**Fig. 19** Effect of GHSV (30,000 h<sup>-1</sup> (■), 50,000 h<sup>-1</sup> (●), 80,000 h<sup>-1</sup> (▲)) on the catalytic activity. (a) NO<sub>x</sub> conversion, (b) THC conversion, (c) CO conversion. Operating conditions: engine speed 3450 rpm, torque 195 Nm (full load), THC/NO<sub>x</sub> ratio 3.4

**Table 2** EURO III ESC test results

Emissions	CO (g/kW h)	THC (g/kW h)	NO <sub>x</sub> (g/kW h)
EURO III limits	2.1	0.66	5.0
Original engine	1.307	0.355	6.924
SCR	3.482	1.431	2.668
SCR + Oxi	0.098	0.709	3.654

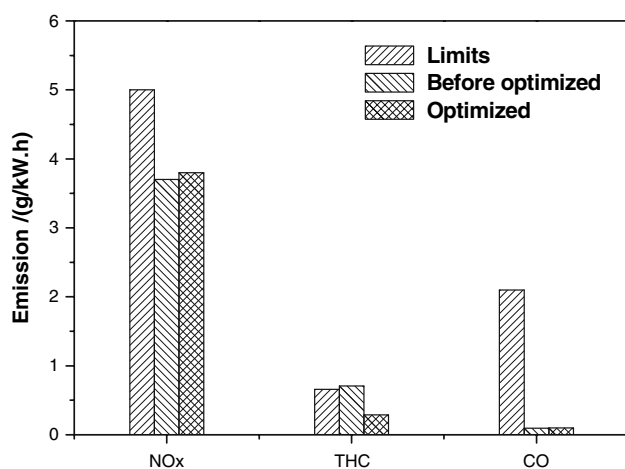

after the SCR catalyst to reduce THC and CO. It can be seen from Table 2 that the SCR + Oxi composite catalyst reduced NO<sub>x</sub> emission, and CO emission was much lower than the EU limits. The HC emission was also reduced from more than twice the limit to just a little higher. Therefore, the SCR + Oxi composite catalyst is more effective than a single SCR catalyst for meeting EURO III regulations. However, because the HC emission still does not meet the EURO III standard, the addition of C<sub>2</sub>H<sub>5</sub>OH should be optimized.

As shown in Fig. 19a, the SCR catalyst showed a high level of activity for NO<sub>x</sub> reduction only in the middle range of temperatures, such as 573–723 K. At lower temperatures (<573 K), the NO<sub>x</sub> conversion was lower, and the addition of C<sub>2</sub>H<sub>5</sub>OH caused a great increase of THC emission without obviously improving the NO<sub>x</sub> conversion. In this case, without adding C<sub>2</sub>H<sub>5</sub>OH, the THC emission would be reduced greatly, although the NO<sub>x</sub> emission would be increased slightly. At higher temperatures (>723 K), NO<sub>x</sub> conversion was also very low. In this case, ambient temperature air could be introduced into the exhaust pipe to reduce the temperature of the exhaust gas to within the temperature range of high NO<sub>x</sub> conversion, and then the NO<sub>x</sub> conversion would be increased.

**Fig. 20** The optimization of C<sub>2</sub>H<sub>5</sub>OH addition

**Fig. 21** Test results after optimization of C<sub>2</sub>H<sub>5</sub>OH addition

According to the 13 operating conditions of EURO III ESC [19], the exhaust temperatures were relatively low at modes 1, 3, 5, 7, 9 and 11, so C<sub>2</sub>H<sub>5</sub>OH was not added due to the low NO<sub>x</sub> emission and conversion. On the other hand, adequate C<sub>2</sub>H<sub>5</sub>OH was added for NO<sub>x</sub> reduction at the high conversion temperature range of modes 2, 4, 6, 8, 12 and 13. In addition, the exhaust temperature was too high at mode 10, so ambient temperature air was introduced along with the addition of C<sub>2</sub>H<sub>5</sub>OH. The strategy of C<sub>2</sub>H<sub>5</sub>OH addition is shown in Fig. 20.

The EURO III ESC test results after optimization are shown in Fig. 21. It was shown that NO<sub>x</sub> and CO emissions are nearly the same as that before optimization, but HC emission is greatly reduced, making the Sofim 8140-43 C diesel engine emissions meet EURO III standards.

## 6 Conclusion

In this review, the SCR of NO<sub>x</sub> with different reductant over Ag/Al<sub>2</sub>O<sub>3</sub> and its application on the diesel engine exhaust cleaning were summarized. The effective order of the oxygenated reductants for the SCR of NO<sub>x</sub> over Ag/Al<sub>2</sub>O<sub>3</sub> is proposed as follows: C4 reductants ≈ C2 reductants > C3 reductants >> C1 reductants. Using C1 reductants, both formate species and nitrate species are the main intermediates, and they have a low level of reactivity with each other to form -NCO species, resulting in low NO<sub>x</sub> reduction with C1 reductants over Ag/Al<sub>2</sub>O<sub>3</sub>. Using C2 or C3 or C4 reductants, the enolic species and nitrates species are the key intermediates, and they have a high level of reactivity with each other to form -NCO species, resulting in high NO<sub>x</sub> reduction with C2, C3 and C4 reductants over Ag/Al<sub>2</sub>O<sub>3</sub>.

The formation of sulfate species on the catalyst resulted in a decrease of the active sites. The comparison between

theoretical and experimental vibration spectra enabled us to draw the following conclusions: bidentate sulfate species rather than tridentate sulfate species are the predominant surface species on Ag/Al<sub>2</sub>O<sub>3</sub>. The accumulation of surface sulfate species could well explain the phenomenon of the blue shift in the IR spectra.

Activity tests showed that the presence of SO<sub>2</sub> in the feed gas can markedly depress the catalytic activity of NO<sub>x</sub> reduction with C3 and C4 reductants. Evidence from the in situ DRIFTS spectra shows that the presence of sulfate species on Ag/Al<sub>2</sub>O<sub>3</sub> not only inhibited the formation of NO<sub>3</sub><sup>-</sup>, but also inhibited the reaction of enolic species with NO<sub>3</sub><sup>-</sup> to form -NCO species, which was responsible for the deactivation of Ag/Al<sub>2</sub>O<sub>3</sub> during the SCR of NO<sub>x</sub> with C3 and C4 reductants in the presence of SO<sub>2</sub>. In contrast, no pronounced deactivation effect of SO<sub>2</sub> was observed when C2 oxygenated reductant was used under the identical experimental conditions. The C2 enolic species formed from the partial oxidation of C2 reductants can inhibit the formation of sulfate species on Ag/Al<sub>2</sub>O<sub>3</sub> in the presence of SO<sub>2</sub>. The relationship between catalyst–reductant system and SO<sub>2</sub> tolerance can be described as below:

In this way, we provide a new idea that it is possible to alter surface reaction to synthesize a SO<sub>2</sub>-resistant surface structure in situ by using different reactants.

The activity of the SCR of NO<sub>x</sub> by hydrocarbon over Ag/Al<sub>2</sub>O<sub>3</sub> was enhanced significantly by the addition of H<sub>2</sub>, especially in the low temperature range of 473–623 K. The addition of H<sub>2</sub> promoted the formation of enolic species during the partial oxidation of hydrocarbon over Ag/Al<sub>2</sub>O<sub>3</sub> catalyst at low temperature. According to our previous studies, this certainly led to the corresponding enhancement of Ag/Al<sub>2</sub>O<sub>3</sub> in the SCR of NO<sub>x</sub> in the presence of H<sub>2</sub>. The addition of H<sub>2</sub> also promoted significantly the activity of NO<sub>x</sub> reduction by oxygenated hydrocarbon over Ag/Al<sub>2</sub>O<sub>3</sub> with a promotional mechanism similar to that mentioned above. As for C<sub>2</sub>H<sub>5</sub>OH as a reductant, the presence of H<sub>2</sub> promoted the formation of enolic species during the partial oxidation of C<sub>2</sub>H<sub>5</sub>OH, and the formation of another active NH<sub>x</sub> species by the hydrolysis of -NCO.

Since the Ag/Al<sub>2</sub>O<sub>3</sub>-C2 reductant system has extremely high efficiency for the SCR of NO<sub>x</sub> and high SO<sub>2</sub> tolerance, it was used for catalytic cleaning of NO<sub>x</sub> in diesel exhaust. Compared with the Ag/Al<sub>2</sub>O<sub>3</sub> granule catalyst, the Ag/Al<sub>2</sub>O<sub>3</sub> washcoated honeycomb catalyst (SCR catalyst) had a similar activity for NO<sub>x</sub> reduction by C<sub>2</sub>H<sub>5</sub>OH in the diesel engine bench test. Using the Cu/Al<sub>2</sub>O<sub>3</sub> washcoated NO<sub>x</sub> catalyst as the oxidation catalyst and matching with

the optimization of C<sub>2</sub>H<sub>5</sub>OH addition, the SCR + Oxi composite catalyst can effectively remove the NO<sub>x</sub>, THC and CO from diesel exhaust and make the emission meet EURO III standards under the 13-mode test cycle.
